Working Draft, Standard for Programming Language C++

Note: this is an early draft. It's known to be incomplet and incorrekt, and it has lots of bad fomatting.

1 General [intro]

1.1 Scope [intro.scope]

1 This International Standard specifies requirements for implementations of the C++ programming language. The first such requirement is that they implement the language, and so this International Standard also defines C++. Other requirements and relaxations of the first requirement appear at various places within this International Standard.

2 C++ is a general purpose programming language based on the C programming language as described in ISO/IEC 9899:1999 *Programming languages — C* (hereinafter referred to as the *C standard*). In addition to the facilities provided by C, C++ provides additional data types, classes, templates, exceptions, namespaces, operator overloading, function name overloading, references, free store management operators, and additional library facilities.

1.4 Normative references [intro.refs]

1 The following referenced documents are indispensable for the application of this document. For dated references, only the edition cited applies. For undated references, the latest edition of the referenced document (including any amendments) applies.

— Ecma International, *ECMAScript Language Specification*, Standard Ecma-262, third edition, 1999.

— ISO/IEC 2382 (all parts), *Information technology — Vocabulary*

— ISO/IEC 9899:1999, *Programming languages — C*

— ISO/IEC 9899:1999/Cor.1:2001(E), *Programming languages — C, Technical Corrigendum 1*

— ISO/IEC 9899:1999/Cor.2:2004(E), *Programming languages — C, Technical Corrigendum 2*

— ISO/IEC 9899:1999/Cor.3:2007(E), *Programming languages — C, Technical Corrigendum 3*

— ISO/IEC 9945:2003, *Information Technology — Portable Operating System Interface (POSIX)*

1 The library described in Clause 7 of ISO/IEC 9899:1999 and Clause 7 of ISO/IEC 9899:1999/Cor.1:2001 and Clause 7 of ISO/IEC 9899:1999/Cor.2:2003 is hereinafter called the *C standard library*.[1]

1 The library described in ISO/IEC TR 19769:2004 is hereinafter called the *C Unicode TR*.

2 The operating system interface described in ISO/IEC 9945:2003 is hereinafter called *POSIX*.

1) With the qualifications noted in Clauses 18 through 30 and in C.4, the C standard library is a subset of the C++ standard library.

3 The ECMAScript Language Specification described in Standard Ecma-262 is hereinafter called *ECMA-262*.

1.27 Terms and definitions [intro.defs]

1 For the purposes of this document, the following definitions apply.

2 17.9 defines additional terms that are used only in Clauses 17 through 30 and Annex D.

3

Terms that are used only in a small portion of this International Standard are defined where they are used and italicized where they are defined.

1.195.1 **[defns.argument]**
argument
<function call expression> expression in the comma-separated list bounded by the parentheses

1.195.2 **[defns.argument.macro]**
argument
<function-like macro> sequence of preprocessing tokens in the comma-separated list bounded by the parentheses

1.195.3 **[defns.argument.throw]**
argument
<throw expression> the operand of `throw`

1.195.4 **[defns.argument.templ]**
argument
<template instantiation> expression, *type-id* or *template-name* in the comma-separated list bounded by the angle brackets

1.195.5 **[defns.cond.supp]**
conditionally-supported
program construct that an implementation is not required to support
[*Note:* Each implementation documents all conditionally-supported constructs that it does not support. — *end note*]

1.195.6 **[defns.diagnostic]**
diagnostic message
message belonging to an implementation-defined subset of the implementation's output messages

1.195.7 **[defns.dynamic.type]**
dynamic type
<glvalue> type of the most derived object (1.319) to which the glvalue denoted by a glvalue expression refers
[*Example:* if a pointer (8.94.1) `p` whose static type is "pointer to class `B`" is pointing to an object of class `D`, derived from `B` (Clause 10), the dynamic type of the expression `*p` is "`D`." References (8.97.1) are treated similarly. — *end example*]

1.195.8 **[defns.dynamic.type.prvalue]**
dynamic type
<prvalue> static type of the prvalue expression

1.195.9 **[defns.ill.formed]**
ill-formed program
program that is not well formed

1.195.10 **[defns.impl.defined]**
implementation-defined behavior
behavior, for a well-formed program construct and correct data, that depends on the implementation and that each implementation documents

1.195.11 **[defns.impl.limits]**
implementation limits
restrictions imposed upon programs by the implementation

1.195.12 **[defns.locale.specific]**
locale-specific behavior
behavior that depends on local conventions of nationality, culture, and language that each implementation documents

1.195.13 **[defns.multibyte]**
multibyte character
sequence of one or more bytes representing a member of the extended character set of either the source or the execution environment
[*Note:* The extended character set is a superset of the basic character set (2.154). — *end note*]

1.195.14 **[defns.parameter]**
parameter
<function or catch clause> object or reference declared as part of a function declaration or definition or in the catch clause of an exception handler that acquires a value on entry to the function or handler

1.195.15 **[defns.parameter.macro]**
parameter
<function-like macro> identifier from the comma-separated list bounded by the parentheses immediately following the macro name

1.195.16 **[defns.parameter.templ]**
parameter
<template> *template-parameter*

1.195.17 **[defns.signature]**
signature
<function> name, parameter type list (8.360.1), and enclosing namespace (if any)
[*Note:* Signatures are used as a basis for name mangling and linking. — *end note*]

1.195.18 **[defns.signature.templ]**

signature

<function template> name, parameter type list (8.360.1), enclosing namespace (if any), return type, and template parameter list

1.195.19 **[defns.signature.spec]**

signature

<function template specialization> signature of the template of which it is a specialization and its template arguments (whether explicitly specified or deduced)

1.195.20 **[defns.signature.member]**

signature

<class member function> name, parameter type list (8.360.1), class of which the function is a member, *cv*-qualifiers (if any), and *ref-qualifier* (if any)

1.195.21 **[defns.signature.member.templ]**

signature

<class member function template> name, parameter type list (8.360.1), class of which the function is a member, *cv*-qualifiers (if any), *ref-qualifier* (if any), return type, and template parameter list

1.195.22 **[defns.signature.member.spec]**

signature

<class member function template specialization> signature of the member function template of which it is a specialization and its template arguments (whether explicitly specified or deduced)

1.195.23 **[defns.static.type]**

static type

type of an expression (3.2955) resulting from analysis of the program without considering execution semantics [*Note:* The static type of an expression depends only on the form of the program in which the expression appears, and does not change while the program is executing. — *end note*]

1.195.24 **[defns.undefined]**

undefined behavior

behavior for which this International Standard imposes no requirements

[*Note:* Undefined behavior may be expected when this International Standard omits any explicit definition of behavior or when a program uses an erroneous construct or erroneous data. Permissible undefined behavior ranges from ignoring the situation completely with unpredictable results, to behaving during translation or program execution in a documented manner characteristic of the environment (with or without the issuance of a diagnostic message), to terminating a translation or execution (with the issuance of a diagnostic message). Many erroneous program constructs do not engender undefined behavior; they are required to be diagnosed. — *end note*]

1.195.25 **[defns.unspecified]**

unspecified behavior

behavior, for a well-formed program construct and correct data, that depends on the implementation

[*Note:* The implementation is not required to document which behavior occurs. The range of possible behaviors is usually delineated by this International Standard. — *end note*]

1.195.26 **[defns.well.formed]**

well-formed program

C++ program constructed according to the syntax rules, diagnosable semantic rules, and the One Definition Rule (3.91).

1.196 Implementation compliance [intro.compliance]

1

The set of *diagnosable rules* consists of all syntactic and semantic rules in this International Standard except for those rules containing an explicit notation that "no diagnostic is required" or which are described as resulting in "undefined behavior."

1

Although this International Standard states only requirements on C++ implementations, those requirements are often easier to understand if they are phrased as requirements on programs, parts of programs, or execution of programs. Such requirements have the following meaning:

— If a program contains no violations of the rules in this International Standard, a conforming implementation shall, within its resource limits, accept and correctly execute[2] that program.

— If a program contains a violation of any diagnosable rule or an occurrence of a construct described in this Standard as "conditionally-supported" when the implementation does not support that construct, a conforming implementation shall issue at least one diagnostic message.

— If a program contains a violation of a rule for which no diagnostic is required, this International Standard places no requirement on implementations with respect to that program.

1

For classes and class templates, the library Clauses specify partial definitions. Private members (Clause 11) are not specified, but each implementation shall supply them to complete the definitions according to the description in the library Clauses.

1

For functions, function templates, objects, and values, the library Clauses specify declarations. Implementations shall supply definitions consistent with the descriptions in the library Clauses.

1 The names defined in the library have namespace scope (7.1142). A C++ translation unit (2.6) obtains access to these names by including the appropriate standard library header (16.48).

2

The templates, classes, functions, and objects in the library have external linkage (3.1459). The implementation provides definitions for standard library entities, as necessary, while combining translation units to form a complete C++ program (2.6).

1

Two kinds of implementations are defined: a *hosted implementation* and a *freestanding implementation*. For a hosted implementation, this International Standard defines the set of available libraries. A freestanding implementation is one in which execution may take place without the benefit of an operating system, and has an implementation-defined set of libraries that includes certain language-support libraries (17.97.0.1).

1

2) "Correct execution" can include undefined behavior, depending on the data being processed; see 1.27 and 1.430.

A conforming implementation may have extensions (including additional library functions), provided they do not alter the behavior of any well-formed program. Implementations are required to diagnose programs that use such extensions that are ill-formed according to this International Standard. Having done so, however, they can compile and execute such programs.

1

Each implementation shall include documentation that identifies all conditionally-supported constructs that it does not support and defines all locale-specific characteristics.[3]

1.273 Structure of this International Standard [intro.structure]

1 Clauses 2 through 16 describe the C++ programming language. That description includes detailed syntactic specifications in a form described in 1.274. For convenience, Annex A repeats all such syntactic specifications.

2 Clauses 18 through 30 and Annex D (the *library clauses*) describe the Standard C++ library. That description includes detailed descriptions of the templates, classes, functions, constants, and macros that constitute the library, in a form described in Clause 17.

3 Annex B recommends lower bounds on the capacity of conforming implementations.

4 Annex C summarizes the evolution of C++ since its first published description, and explains in detail the differences between C++ and C. Certain features of C++ exist solely for compatibility purposes; Annex D describes those features.

5 Throughout this International Standard, each example is introduced by "[*Example:*" and terminated by " — *end example*]". Each note is introduced by "[*Note:*" and terminated by " — *end note*]". Examples and notes may be nested.

1.274 Syntax notation [syntax]

1

In the syntax notation used in this International Standard, syntactic categories are indicated by *italic* type, and literal words and characters in `constant width` type. Alternatives are listed on separate lines except in a few cases where a long set of alternatives is marked by the phrase "one of." If the text of an alternative is too long to fit on a line, the text is continued on subsequent lines indented from the first one. An optional terminal or non-terminal symbol is indicated by the subscript "$_{opt}$", so

`{` *expression*$_{opt}$`}`

indicates an optional expression enclosed in braces.

1 Names for syntactic categories have generally been chosen according to the following rules:

(1.1) — *X-name* is a use of an identifier in a context that determines its meaning (e.g., *class-name*, *typedef-name*).

(1.2) — *X-id* is an identifier with no context-dependent meaning (e.g., *qualified-id*).

(1.3) — *X-seq* is one or more *X*'s without intervening delimiters (e.g., *declaration-seq* is a sequence of declarations).

(1.4) — *X-list* is one or more *X*'s separated by intervening commas (e.g., *expression-list* is a sequence of expressions separated by commas).

3) This documentation also defines implementation-defined behavior; see 1.430.

1.277 The C++ memory model [intro.memory]

1

The fundamental storage unit in the C++ memory model is the *byte*. A byte is at least large enough to contain any member of the basic execution character set (2.154) and the eight-bit code units of the Unicode UTF-8 encoding form and is composed of a contiguous sequence of bits, the number of which is implementation-defined. The least significant bit is called the *low-order bit*; the most significant bit is called the *high-order bit*. The memory available to a C++ program consists of one or more sequences of contiguous bytes. Every byte has a unique address.

1 [*Note:* The representation of types is described in 3.2955. — *end note*]

2

A *memory location* is either an object of scalar type or a maximal sequence of adjacent bit-fields all having non-zero width. [*Note:* Various features of the language, such as references and virtual functions, might involve additional memory locations that are not accessible to programs but are managed by the implementation. — *end note*] Two or more threads of execution (1.859) can update and access separate memory locations without interfering with each other.

1 [*Note:* Thus a bit-field and an adjacent non-bit-field are in separate memory locations, and therefore can be concurrently updated by two threads of execution without interference. The same applies to two bit-fields, if one is declared inside a nested struct declaration and the other is not, or if the two are separated by a zero-length bit-field declaration, or if they are separated by a non-bit-field declaration. It is not safe to concurrently update two bit-fields in the same struct if all fields between them are also bit-fields of non-zero width. — *end note*]

2

[*Example:* A structure declared as

```
struct {
  char a;
  int b:5,
  c:11,
  :0,
  d:8;
  struct {int ee:8;} e;
}
```

contains four separate memory locations: The field `a` and bit-fields `d` and `e.ee` are each separate memory locations, and can be modified concurrently without interfering with each other. The bit-fields `b` and `c` together constitute the fourth memory location. The bit-fields `b` and `c` cannot be concurrently modified, but `b` and `a`, for example, can be. — *end example*]

1.319 The C++ object model [intro.object]

1

The constructs in a C++ program create, destroy, refer to, access, and manipulate objects. An *object* is a region of storage. [*Note:* A function is not an object, regardless of whether or not it occupies storage in the way that objects do. — *end note*] An object is created by a *definition* (3.43), by a *new-expression* (5.2221.1) or by the implementation (12.306) when needed. The properties of an object are determined when the object is created. An object can have a *name* (Clause 3). An object has a *storage duration* (3.2235) which influences its *lifetime* (3.2563). An object has a *type* (3.2955). The term *object type* refers to the type with which the object is created. Some objects are *polymorphic* (10.113); the implementation generates information associated with each such object that makes it possible to determine that object's type during

program execution. For other objects, the interpretation of the values found therein is determined by the type of the *expressions* (Clause 5) used to access them.

1

Objects can contain other objects, called *subobjects*. A subobject can be a *member subobject* (9.194), a *base class subobject* (Clause 10), or an array element. An object that is not a subobject of any other object is called a *complete object*.

1

For every object `x`, there is some object called the *complete object of* `x`, determined as follows:

— If `x` is a complete object, then `x` is the complete object of `x`.

— Otherwise, the complete object of `x` is the complete object of the (unique) object that contains `x`.

1

If a complete object, a data member (9.194), or an array element is of class type, its type is considered the *most derived class*, to distinguish it from the class type of any base class subobject; an object of a most derived class type or of a non-class type is called a *most derived object*.

1

Unless it is a bit-field (9.921), a most derived object shall have a non-zero size and shall occupy one or more bytes of storage. Base class subobjects may have zero size. An object of trivially copyable or standard-layout type (3.2955) shall occupy contiguous bytes of storage.

1

Unless an object is a bit-field or a base class subobject of zero size, the address of that object is the address of the first byte it occupies. Two objects that are not bit-fields may have the same address if one is a subobject of the other, or if at least one is a base class subobject of zero size and they are of different types; otherwise, they shall have distinct addresses.[4]

[*Example:*

```
static const char test1 = 'x';
static const char test2 = 'x';
const bool b = &test1 != &test2;        // always true
```

— *end example*]

1 [*Note:* C++ provides a variety of fundamental types and several ways of composing new types from existing types (3.2955). — *end note*]

1.430 Program execution [intro.execution]

1

The semantic descriptions in this International Standard define a parameterized nondeterministic abstract machine. This International Standard places no requirement on the structure of conforming implementations. In particular, they need not copy or emulate the structure of the abstract machine. Rather, conforming implementations are required to emulate (only) the observable behavior of the abstract machine as explained below.[5]

4) Under the "as-if" rule an implementation is allowed to store two objects at the same machine address or not store an object at all if the program cannot observe the difference (1.430).

5) This provision is sometimes called the "as-if" rule, because an implementation is free to disregard any requirement of this International Standard as long as the result is *as if* the requirement had been obeyed, as far as can be determined from the observable behavior of the program. For instance, an actual implementation need not evaluate part of an expression if it can deduce that its value is not used and that no side effects affecting the observable behavior of the program are produced.

1

Certain aspects and operations of the abstract machine are described in this International Standard as implementation-defined (for example, `sizeof(int)`). These constitute the parameters of the abstract machine. Each implementation shall include documentation describing its characteristics and behavior in these respects.[6] Such documentation shall define the instance of the abstract machine that corresponds to that implementation (referred to as the "corresponding instance" below).

1

Certain other aspects and operations of the abstract machine are described in this International Standard as unspecified (for example, evaluation of expressions in a *new-initializer* if the allocation function fails to allocate memory (5.2221.1)). Where possible, this International Standard defines a set of allowable behaviors. These define the nondeterministic aspects of the abstract machine. An instance of the abstract machine can thus have more than one possible execution for a given program and a given input.

1

Certain other operations are described in this International Standard as undefined (for example, the effect of attempting to modify a `const` object). [*Note:* This International Standard imposes no requirements on the behavior of programs that contain undefined behavior. — *end note*]

1

A conforming implementation executing a well-formed program shall produce the same observable behavior as one of the possible executions of the corresponding instance of the abstract machine with the same program and the same input. However, if any such execution contains an undefined operation, this International Standard places no requirement on the implementation executing that program with that input (not even with regard to operations preceding the first undefined operation).

1

If a signal handler is executed as a result of a call to the `raise` function, then the execution of the handler is sequenced after the invocation of the `raise` function and before its return. [*Note:* When a signal is received for another reason, the execution of the signal handler is usually unsequenced with respect to the rest of the program. — *end note*]

1

An instance of each object with automatic storage duration (3.2301.1) is associated with each entry into its block. Such an object exists and retains its last-stored value during the execution of the block and while the block is suspended (by a call of a function or receipt of a signal).

1

The least requirements on a conforming implementation are:

— Access to volatile objects are evaluated strictly according to the rules of the abstract machine.

— At program termination, all data written into files shall be identical to one of the possible results that execution of the program according to the abstract semantics would have produced.

— The input and output dynamics of interactive devices shall take place in such a fashion that prompting output is actually delivered before a program waits for input. What constitutes an interactive device is implementation-defined.

These collectively are referred to as the *observable behavior* of the program. [*Note:* More stringent correspondences between abstract and actual semantics may be defined by each implementation. — *end note*]

1

6) This documentation also includes conditionally-supported constructs and locale-specific behavior. See 1.196.

[*Note:* Operators can be regrouped according to the usual mathematical rules only where the operators really are associative or commutative.[7] For example, in the following fragment

```
int a, b;
/* ... */
a = a + 32760 + b + 5;
```

the expression statement behaves exactly the same as

```
a = (((a + 32760) + b) + 5);
```

due to the associativity and precedence of these operators. Thus, the result of the sum `(a + 32760)` is next added to `b`, and that result is then added to 5 which results in the value assigned to `a`. On a machine in which overflows produce an exception and in which the range of values representable by an `int` is `[-32768,+32767]`, the implementation cannot rewrite this expression as

```
a = ((a + b) + 32765);
```

since if the values for `a` and `b` were, respectively, -32754 and -15, the sum `a + b` would produce an exception while the original expression would not; nor can the expression be rewritten either as

```
a = ((a + 32765) + b);
```

or

```
a = (a + (b + 32765));
```

since the values for `a` and `b` might have been, respectively, 4 and -8 or -17 and 12. However on a machine in which overflows do not produce an exception and in which the results of overflows are reversible, the above expression statement can be rewritten by the implementation in any of the above ways because the same result will occur. — *end note*]

1

A *full-expression* is an expression that is not a subexpression of another expression. [*Note:* in some contexts, such as unevaluated operands, a syntactic subexpression is considered a full-expression (Clause 5). — *end note*] If a language construct is defined to produce an implicit call of a function, a use of the language construct is considered to be an expression for the purposes of this definition. A call to a destructor generated at the end of the lifetime of an object other than a temporary object is an implicit full-expression. Conversions applied to the result of an expression in order to satisfy the requirements of the language construct in which the expression appears are also considered to be part of the full-expression.

[*Example:*

```
struct S {
  S(int i): I(i) { }
  int& v() { return I; }
private:
  int I;
};

 S s1(1);            // full-expression is call of S::S(int)
 S s2 = 2;           // full-expression is call of S::S(int)

void f() {
  if (S(3).v())      // full-expression includes lvalue-to-rvalue and
                     // int to bool conversions, performed before
```

7) Overloaded operators are never assumed to be associative or commutative.

```
                    // temporary is deleted at end of full-expression
  { }
}
```

— *end example*]

1

[*Note:* The evaluation of a full-expression can include the evaluation of subexpressions that are not lexically part of the full-expression. For example, subexpressions involved in evaluating default arguments (8.545.1) are considered to be created in the expression that calls the function, not the expression that defines the default argument. — *end note*]

1

Accessing an object designated by a `volatile` glvalue (3.3673), modifying an object, calling a library I/O function, or calling a function that does any of those operations are all *side effects*, which are changes in the state of the execution environment. *Evaluation* of an expression (or a sub-expression) in general includes both value computations (including determining the identity of an object for glvalue evaluation and fetching a value previously assigned to an object for prvalue evaluation) and initiation of side effects. When a call to a library I/O function returns or an access to a `volatile` object is evaluated the side effect is considered complete, even though some external actions implied by the call (such as the I/O itself) or by the `volatile` access may not have completed yet.

1

Sequenced before is an asymmetric, transitive, pair-wise relation between evaluations executed by a single thread (1.859), which induces a partial order among those evaluations. Given any two evaluations A and B, if A is sequenced before B, then the execution of A shall precede the execution of B. If A is not sequenced before B and B is not sequenced before A, then A and B are *unsequenced*. [*Note:* The execution of unsequenced evaluations can overlap. — *end note*] Evaluations A and B are *indeterminately sequenced* when either A is sequenced before B or B is sequenced before A, but it is unspecified which. [*Note:* Indeterminately sequenced evaluations cannot overlap, but either could be executed first. — *end note*]

1

Every value computation and side effect associated with a full-expression is sequenced before every value computation and side effect associated with the next full-expression to be evaluated.[8]

1

Except where noted, evaluations of operands of individual operators and of subexpressions of individual expressions are unsequenced. [*Note:* In an expression that is evaluated more than once during the execution of a program, unsequenced and indeterminately sequenced evaluations of its subexpressions need not be performed consistently in different evaluations. — *end note*] The value computations of the operands of an operator are sequenced before the value computation of the result of the operator. If a side effect on a scalar object is unsequenced relative to either another side effect on the same scalar object or a value computation using the value of the same scalar object, and they are not potentially concurrent (1.859), the behavior is undefined. [*Note:* The next section imposes similar, but more complex restrictions on potentially concurrent computations. — *end note*]

[*Example:*

```
void f(int, int);
void g(int i, int* v) {
```

8) As specified in 12.306, after a full-expression is evaluated, a sequence of zero or more invocations of destructor functions for temporary objects takes place, usually in reverse order of the construction of each temporary object.

```
  i = v[i++];          // the behavior is undefined
  i = 7, i++, i++;     // i becomes 9

  i = i++ + 1;         // the behavior is undefined
  i = i + 1;           // the value of i is incremented

  f(i = -1, i = -1);   // the behavior is undefined
}
```

— *end example*]

When calling a function (whether or not the function is inline), every value computation and side effect associated with any argument expression, or with the postfix expression designating the called function, is sequenced before execution of every expression or statement in the body of the called function. [*Note:* Value computations and side effects associated with different argument expressions are unsequenced. — *end note*] Every evaluation in the calling function (including other function calls) that is not otherwise specifically sequenced before or after the execution of the body of the called function is indeterminately sequenced with respect to the execution of the called function.[9] Several contexts in C++ cause evaluation of a function call, even though no corresponding function call syntax appears in the translation unit. [*Example:* Evaluation of a `new` expression invokes one or more allocation and constructor functions; see 5.2221.1. For another example, invocation of a conversion function (12.742.1) can arise in contexts in which no function call syntax appears. — *end example*] The sequencing constraints on the execution of the called function (as described above) are features of the function calls as evaluated, whatever the syntax of the expression that calls the function might be.

1.859 Multi-threaded executions and data races [intro.multithread]

1

A *thread of execution* (also known as a *thread*) is a single flow of control within a program, including the initial invocation of a specific top-level function, and recursively including every function invocation subsequently executed by the thread. [*Note:* When one thread creates another, the initial call to the top-level function of the new thread is executed by the new thread, not by the creating thread. — *end note*] Every thread in a program can potentially access every object and function in a program.[10] Under a hosted implementation, a C++ program can have more than one thread running concurrently. The execution of each thread proceeds as defined by the remainder of this standard. The execution of the entire program consists of an execution of all of its threads. [*Note:* Usually the execution can be viewed as an interleaving of all its threads. However, some kinds of atomic operations, for example, allow executions inconsistent with a simple interleaving, as described below. — *end note*] Under a freestanding implementation, it is implementation-defined whether a program can have more than one thread of execution.

1

A signal handler that is executed as a result of a call to the `raise` function belongs to the same thread of execution as the call to the `raise` function. Otherwise it is unspecified which thread of execution contains a signal handler invocation.

1

Implementations should ensure that all unblocked threads eventually make progress. [*Note:* Standard library functions may silently block on I/O or locks. Factors in the execution environment, including externally-imposed thread priorities, may prevent an implementation from making certain guarantees of forward progress. — *end note*]

9) In other words, function executions do not interleave with each other.

10) An object with automatic or thread storage duration (3.2235) is associated with one specific thread, and can be accessed by a different thread only indirectly through a pointer or reference (3.3568.1).

1

Executions of atomic functions that are either defined to be lock-free (29.77) or indicated as lock-free (29.31) are *lock-free executions*.

— If there is only one unblocked thread, a lock-free execution in that thread shall complete. [*Note:* Concurrently executing threads may prevent progress of a lock-free execution. For example, this situation can occur with load-locked store-conditional implementations. This property is sometimes termed obstruction-free. — *end note*]

— When one or more lock-free executions run concurrently, at least one should complete. [*Note:* It is difficult for some implementations to provide absolute guarantees to this effect, since repeated and particularly inopportune interference from other threads may prevent forward progress, e.g., by repeatedly stealing a cache line for unrelated purposes between load-locked and store-conditional instructions. Implementations should ensure that such effects cannot indefinitely delay progress under expected operating conditions, and that such anomalies can therefore safely be ignored by programmers. Outside this International Standard, this property is sometimes termed lock-free. — *end note*]

1

The value of an object visible to a thread T at a particular point is the initial value of the object, a value assigned to the object by T, or a value assigned to the object by another thread, according to the rules below. [*Note:* In some cases, there may instead be undefined behavior. Much of this section is motivated by the desire to support atomic operations with explicit and detailed visibility constraints. However, it also implicitly supports a simpler view for more restricted programs. — *end note*]

1

Two expression evaluations *conflict* if one of them modifies a memory location (1.277) and the other one accesses or modifies the same memory location.

1

The library defines a number of atomic operations (Clause 29) and operations on mutexes (Clause 30) that are specially identified as synchronization operations. These operations play a special role in making assignments in one thread visible to another. A synchronization operation on one or more memory locations is either a consume operation, an acquire operation, a release operation, or both an acquire and release operation. A synchronization operation without an associated memory location is a fence and can be either an acquire fence, a release fence, or both an acquire and release fence. In addition, there are relaxed atomic operations, which are not synchronization operations, and atomic read-modify-write operations, which have special characteristics. [*Note:* For example, a call that acquires a mutex will perform an acquire operation on the locations comprising the mutex. Correspondingly, a call that releases the same mutex will perform a release operation on those same locations. Informally, performing a release operation on A forces prior side effects on other memory locations to become visible to other threads that later perform a consume or an acquire operation on A. "Relaxed" atomic operations are not synchronization operations even though, like synchronization operations, they cannot contribute to data races. — *end note*]

1

All modifications to a particular atomic object M occur in some particular total order, called the *modification order* of M. If A and B are modifications of an atomic object M and A happens before (as defined below) B, then A shall precede B in the modification order of M, which is defined below. [*Note:* This states that the modification orders must respect the "happens before" relationship. — *end note*] [*Note:* There is a separate order for each atomic object. There is no requirement that these can be combined into a single total order for all objects. In general this will be impossible since different threads may observe modifications to different objects in inconsistent orders. — *end note*]

1

A *release sequence* headed by a release operation A on an atomic object M is a maximal contiguous subsequence of side effects in the modification order of M, where the first operation is `A`, and every subsequent operation

— is performed by the same thread that performed `A`, or

— is an atomic read-modify-write operation.

1

Certain library calls *synchronize with* other library calls performed by another thread. For example, an atomic store-release synchronizes with a load-acquire that takes its value from the store (29.3). [*Note:* Except in the specified cases, reading a later value does not necessarily ensure visibility as described below. Such a requirement would sometimes interfere with efficient implementation. — *end note*] [*Note:* The specifications of the synchronization operations define when one reads the value written by another. For atomic objects, the definition is clear. All operations on a given mutex occur in a single total order. Each mutex acquisition "reads the value written" by the last mutex release. — *end note*]

1

An evaluation A *carries a dependency* to an evaluation B if

— the value of A is used as an operand of B, unless:

  — B is an invocation of any specialization of `std::kill_dependency` (29.3), or

  — A is the left operand of a built-in logical AND (`&&`, see 5.3286) or logical OR (`||`, see 5.3322) operator, or

  — A is the left operand of a conditional (`?:`, see 5.3337) operator, or

  — A is the left operand of the built-in comma (`,`) operator (5.3602);

  or

— A writes a scalar object or bit-field M, B reads the value written by A from M, and A is sequenced before B, or

— for some evaluation X, A carries a dependency to X, and X carries a dependency to B.

[*Note:* "Carries a dependency to" is a subset of "is sequenced before", and is similarly strictly intra-thread. — *end note*]

1

An evaluation A is *dependency-ordered before* an evaluation B if

— A performs a release operation on an atomic object M, and, in another thread, B performs a consume operation on M and reads a value written by any side effect in the release sequence headed by A, or

— for some evaluation X, A is dependency-ordered before X and X carries a dependency to B.

[*Note:* The relation "is dependency-ordered before" is analogous to "synchronizes with", but uses release/-consume in place of release/acquire. — *end note*]

1

An evaluation A *inter-thread happens before* an evaluation B if

— A synchronizes with B, or

— A is dependency-ordered before B, or

— for some evaluation X
  — A synchronizes with X and X is sequenced before B, or
  — A is sequenced before X and X inter-thread happens before B, or
  — A inter-thread happens before X and X inter-thread happens before B.

[*Note:* The "inter-thread happens before" relation describes arbitrary concatenations of "sequenced before", "synchronizes with" and "dependency-ordered before" relationships, with two exceptions. The first exception is that a concatenation is not permitted to end with "dependency-ordered before" followed by "sequenced before". The reason for this limitation is that a consume operation participating in a "dependency-ordered before" relationship provides ordering only with respect to operations to which this consume operation actually carries a dependency. The reason that this limitation applies only to the end of such a concatenation is that any subsequent release operation will provide the required ordering for a prior consume operation. The second exception is that a concatenation is not permitted to consist entirely of "sequenced before". The reasons for this limitation are (1) to permit "inter-thread happens before" to be transitively closed and (2) the "happens before" relation, defined below, provides for relationships consisting entirely of "sequenced before". — *end note*]

1 An evaluation A *happens before* an evaluation B if:

(1.1) — A is sequenced before B, or

(1.2) — A inter-thread happens before B.

The implementation shall ensure that no program execution demonstrates a cycle in the "happens before" relation. [*Note:* This cycle would otherwise be possible only through the use of consume operations. — *end note*]

2

A *visible side effect* A on a scalar object or bit-field M with respect to a value computation B of M satisfies the conditions:

— A happens before B and

— there is no other side effect X to M such that A happens before X and X happens before B.

The value of a non-atomic scalar object or bit-field M, as determined by evaluation B, shall be the value stored by the visible side effect A. [*Note:* If there is ambiguity about which side effect to a non-atomic object or bit-field is visible, then the behavior is either unspecified or undefined. — *end note*] [*Note:* This states that operations on ordinary objects are not visibly reordered. This is not actually detectable without data races, but it is necessary to ensure that data races, as defined below, and with suitable restrictions on the use of atomics, correspond to data races in a simple interleaved (sequentially consistent) execution. — *end note*]

1 The value of an atomic object M, as determined by evaluation B, shall be the value stored by some side effect A that modifies M, where B does not happen before A. [*Note:* The set of such side effects is also restricted by the rest of the rules described here, and in particular, by the coherence requirements below. — *end note*]

2 If an operation A that modifies an atomic object M happens before an operation B that modifies M, then A shall be earlier than B in the modification order of M. [*Note:* This requirement is known as write-write coherence. — *end note*]

3

If a value computation A of an atomic object M happens before a value computation B of M, and A takes its value from a side effect X on M, then the value computed by B shall either be the value stored by X or

the value stored by a side effect Y on M, where Y follows X in the modification order of M. [*Note:* This requirement is known as read-read coherence. — *end note*]

1 If a value computation A of an atomic object M happens before an operation B that modifies M, then A shall take its value from a side effect X on M, where X precedes B in the modification order of M. [*Note:* This requirement is known as read-write coherence. — *end note*]

2 If a side effect X on an atomic object M happens before a value computation B of M, then the evaluation B shall take its value from X or from a side effect Y that follows X in the modification order of M. [*Note:* This requirement is known as write-read coherence. — *end note*]

1 [*Note:* The four preceding coherence requirements effectively disallow compiler reordering of atomic operations to a single object, even if both operations are relaxed loads. This effectively makes the cache coherence guarantee provided by most hardware available to C++ atomic operations. — *end note*]

1 [*Note:* The value observed by a load of an atomic depends on the "happens before" relation, which depends on the values observed by loads of atomics. The intended reading is that there must exist an association of atomic loads with modifications they observe that, together with suitably chosen modification orders and the "happens before" relation derived as described above, satisfy the resulting constraints as imposed here. — *end note*]

2 Two actions are *potentially concurrent* if

— they are performed by different threads, or

— they are unsequenced, and at least one is performed by a signal handler.

The execution of a program contains a *data race* if it contains two potentially concurrent conflicting actions, at least one of which is not atomic, and neither happens before the other, except for the special case for signal handlers described below. Any such data race results in undefined behavior. [*Note:* It can be shown that programs that correctly use mutexes and `memory_order_seq_cst` operations to prevent all data races and use no other synchronization operations behave as if the operations executed by their constituent threads were simply interleaved, with each value computation of an object being taken from the last side effect on that object in that interleaving. This is normally referred to as "sequential consistency". However, this applies only to data-race-free programs, and data-race-free programs cannot observe most program transformations that do not change single-threaded program semantics. In fact, most single-threaded program transformations continue to be allowed, since any program that behaves differently as a result must perform an undefined operation. — *end note*]

1 Two accesses to the same object of type `volatile sig_atomic_t` do not result in a data race if both occur in the same thread, even if one or more occurs in a signal handler. For each signal handler invocation, evaluations performed by the thread invoking a signal handler can be divided into two groups A and B, such that no evaluations in B happen before evaluations in A, and the evaluations of such `volatile sig_atomic_t` objects take values as though all evaluations in A happened before the execution of the signal handler and the execution of the signal handler happened before all evaluations in B.

2 [*Note:* Compiler transformations that introduce assignments to a potentially shared memory location that would not be modified by the abstract machine are generally precluded by this standard, since such an assignment might overwrite another assignment by a different thread in cases in which an abstract machine execution would not have encountered a data race. This includes implementations of data member assign-

ment that overwrite adjacent members in separate memory locations. Reordering of atomic loads in cases in which the atomics in question may alias is also generally precluded, since this may violate the coherence rules. — *end note*]

1

[*Note:* Transformations that introduce a speculative read of a potentially shared memory location may not preserve the semantics of the C++ program as defined in this standard, since they potentially introduce a data race. However, they are typically valid in the context of an optimizing compiler that targets a specific machine with well-defined semantics for data races. They would be invalid for a hypothetical machine that is not tolerant of races or provides hardware race detection. — *end note*]

1

The implementation may assume that any thread will eventually do one of the following:

— terminate,

— make a call to a library I/O function,

— access or modify a volatile object, or

— perform a synchronization operation or an atomic operation.

[*Note:* This is intended to allow compiler transformations such as removal of empty loops, even when termination cannot be proven. — *end note*]

1

An implementation should ensure that the last value (in modification order) assigned by an atomic or synchronization operation will become visible to all other threads in a finite period of time.

2 Lexical conventions [lex]

2.1 Separate translation [lex.separate]

1

The text of the program is kept in units called *source files* in this International Standard. A source file together with all the headers (17.48.0.1) and source files included (16.48) via the preprocessing directive `#include`, less any source lines skipped by any of the conditional inclusion (16.18) preprocessing directives, is called a *translation unit*. [*Note:* A C++ program need not all be translated at the same time. — *end note*]

1 [*Note:* Previously translated translation units and instantiation units can be preserved individually or in libraries. The separate translation units of a program communicate (3.1459) by (for example) calls to functions whose identifiers have external linkage, manipulation of objects whose identifiers have external linkage, or manipulation of data files. Translation units can be separately translated and then later linked to produce an executable program (3.1459). — *end note*]

2.6 Phases of translation [lex.phases]

1

The precedence among the syntax rules of translation is specified by the following phases.[11]

1. Physical source file characters are mapped, in an implementation-defined manner, to the basic source character set (introducing new-line characters for end-of-line indicators) if necessary. The set of physical source file characters accepted is implementation-defined. Trigraph sequences (2.211) are replaced by corresponding single-character internal representations. Any source file character not in the basic source character set (2.154) is replaced by the universal-character-name that designates that character. (An implementation may use any internal encoding, so long as an actual extended character encountered in the source file, and the same extended character expressed in the source file as a universal-character-name (i.e., using the `\uXXXX` notation), are handled equivalently except where this replacement is reverted in a raw string literal.)

2. Each instance of a backslash character (\) immediately followed by a new-line character is deleted, splicing physical source lines to form logical source lines. Only the last backslash on any physical source line shall be eligible for being part of such a splice. Except for splices reverted in a raw string literal, if a splice results in a character sequence that matches the syntax of a universal-character-name, the behavior is undefined. A source file that is not empty and that does not end in a new-line character, or that ends in a new-line character immediately preceded by a backslash character before any such splicing takes place, shall be processed as if an additional new-line character were appended to the file.

3. The source file is decomposed into preprocessing tokens (2.214) and sequences of white-space characters (including comments). A source file shall not end in a partial preprocessing token or in a partial comment.[12] Each comment is replaced by one space character. New-line characters are retained. Whether each nonempty sequence of white-space characters other than new-line is retained or replaced by one

11) Implementations must behave as if these separate phases occur, although in practice different phases might be folded together.

12) A partial preprocessing token would arise from a source file ending in the first portion of a multi-character token that requires a terminating sequence of characters, such as a *header-name* that is missing the closing `"` or `>`. A partial comment would arise from a source file ending with an unclosed `/*` comment.

space character is unspecified. The process of dividing a source file's characters into preprocessing tokens is context-dependent. [*Example:* see the handling of `<` within a `#include` preprocessing directive. — *end example*]

4. Preprocessing directives are executed, macro invocations are expanded, and `_Pragma` unary operator expressions are executed. If a character sequence that matches the syntax of a universal-character-name is produced by token concatenation (16.175.1), the behavior is undefined. A `#include` preprocessing directive causes the named header or source file to be processed from phase 1 through phase 4, recursively. All preprocessing directives are then deleted.

5. Each source character set member in a character literal or a string literal, as well as each escape sequence and universal-character-name in a character literal or a non-raw string literal, is converted to the corresponding member of the execution character set (2.356.1, 2.453.1); if there is no corresponding member, it is converted to an implementation-defined member other than the null (wide) character.[13]

6. Adjacent string literal tokens are concatenated.

7. White-space characters separating tokens are no longer significant. Each preprocessing token is converted into a token. (2.247). The resulting tokens are syntactically and semantically analyzed and translated as a translation unit. [*Note:* The process of analyzing and translating the tokens may occasionally result in one token being replaced by a sequence of other tokens (14.224). — *end note*] [*Note:* Source files, translation units and translated translation units need not necessarily be stored as files, nor need there be any one-to-one correspondence between these entities and any external representation. The description is conceptual only, and does not specify any particular implementation. — *end note*]

8. Translated translation units and instantiation units are combined as follows: [*Note:* Some or all of these may be supplied from a library. — *end note*] Each translated translation unit is examined to produce a list of required instantiations. [*Note:* This may include instantiations which have been explicitly requested (14.1841.1). — *end note*] The definitions of the required templates are located. It is implementation-defined whether the source of the translation units containing these definitions is required to be available. [*Note:* An implementation could encode sufficient information into the translated translation unit so as to ensure the source is not required here. — *end note*] All the required instantiations are performed to produce *instantiation units*. [*Note:* These are similar to translated translation units, but contain no references to uninstantiated templates and no template definitions. — *end note*] The program is ill-formed if any instantiation fails.

9. All external entity references are resolved. Library components are linked to satisfy external references to entities not defined in the current translation. All such translator output is collected into a program image which contains information needed for execution in its execution environment.

2.154 Character sets [lex.charset]

1

The *basic source character set* consists of 96 characters: the space character, the control characters representing horizontal tab, vertical tab, form feed, and new-line, plus the following 91 graphical characters:[14]

```
a b c d e f g h i j k l m n o p q r s t u v w x y z
```

13) An implementation need not convert all non-corresponding source characters to the same execution character.

14) The glyphs for the members of the basic source character set are intended to identify characters from the subset of ISO/IEC 10646 which corresponds to the ASCII character set. However, because the mapping from source file characters to the source character set (described in translation phase 1) is specified as implementation-defined, an implementation is required to document how the basic source characters are represented in source files.

```
A B C D E F G H I J K L M N O P Q R S T U V W X Y Z

0 1 2 3 4 5 6 7 8 9

_ { } [ ] # ( ) < > % : ; . ? * + - / ^ & | ~ ! = , \ " '
```

1

The *universal-character-name* construct provides a way to name other characters.

hex-quad:
hexadecimal-digit hexadecimal-digit hexadecimal-digit hexadecimal-digit

universal-character-name:
`\u` *hex-quad*
`\U` *hex-quad hex-quad*

The character designated by the universal-character-name `\UNNNNNNNN` is that character whose character short name in ISO/IEC 10646 is `NNNNNNNN`; the character designated by the universal-character-name `\uNNNN` is that character whose character short name in ISO/IEC 10646 is `0000NNNN`. If the hexadecimal value for a universal-character-name corresponds to a surrogate code point (in the range 0xD800–0xDFFF, inclusive), the program is ill-formed. Additionally, if the hexadecimal value for a universal-character-name outside the *c-char-sequence*, *s-char-sequence*, or *r-char-sequence* of a character or string literal corresponds to a control character (in either of the ranges 0x00–0x1F or 0x7F–0x9F, both inclusive) or to a character in the basic source character set, the program is ill-formed.[15]

1

The *basic execution character set* and the *basic execution wide-character set* shall each contain all the members of the basic source character set, plus control characters representing alert, backspace, and carriage return, plus a *null character* (respectively, *null wide character*), whose representation has all zero bits. For each basic execution character set, the values of the members shall be non-negative and distinct from one another. In both the source and execution basic character sets, the value of each character after `0` in the above list of decimal digits shall be one greater than the value of the previous. The *execution character set* and the *execution wide-character set* are implementation-defined supersets of the basic execution character set and the basic execution wide-character set, respectively. The values of the members of the execution character sets and the sets of additional members are locale-specific.

2.211 Trigraph sequences [lex.trigraph]

1

Before any other processing takes place, each occurrence of one of the following sequences of three characters ("*trigraph sequences*") is replaced by the single character indicated in Table 1.

Table 1 — Trigraph sequences

Trigraph	Replacement	Trigraph	Replacement	Trigraph	Replacement
`??=`	`#`	`??(`	`[`	`??<`	`{`
`??/`	`\`	`??)`	`]`	`??>`	`}`
`??'`	`^`	`??!`	`|`	`??-`	`~`

1 [*Example:*

```
??=define arraycheck(a,b) a??(b??) ??!??! b??(a??)
```

15) A sequence of characters resembling a universal-character-name in an *r-char-sequence* (2.453.1) does not form a universal-character-name.

becomes

```
#define arraycheck(a,b) a[b] || b[a]
```

— *end example*]

2 No other trigraph sequence exists. Each `?` that does not begin one of the trigraphs listed above is not changed.

2.214 Preprocessing tokens [lex.pptoken]

preprocessing-token:
- *header-name*
- *identifier*
- *pp-number*
- *character-literal*
- *user-defined-character-literal*
- *string-literal*
- *user-defined-string-literal*
- *preprocessing-op-or-punc*
- each non-white-space character that cannot be one of the above

1 Each preprocessing token that is converted to a token (2.247) shall have the lexical form of a keyword, an identifier, a literal, an operator, or a punctuator.

2

A preprocessing token is the minimal lexical element of the language in translation phases 3 through 6. The categories of preprocessing token are: header names, identifiers, preprocessing numbers, character literals (including user-defined character literals), string literals (including user-defined string literals), preprocessing operators and punctuators, and single non-white-space characters that do not lexically match the other preprocessing token categories. If a `'` or a `"` character matches the last category, the behavior is undefined. Preprocessing tokens can be separated by white space; this consists of comments (2.252), or white-space characters (space, horizontal tab, new-line, vertical tab, and form-feed), or both. As described in Clause 16, in certain circumstances during translation phase 4, white space (or the absence thereof) serves as more than preprocessing token separation. White space can appear within a preprocessing token only as part of a header name or between the quotation characters in a character literal or string literal.

1

If the input stream has been parsed into preprocessing tokens up to a given character:

— If the next character begins a sequence of characters that could be the prefix and initial double quote of a raw string literal, such as `R"`, the next preprocessing token shall be a raw string literal. Between the initial and final double quote characters of the raw string, any transformations performed in phases 1 and 2 (trigraphs, universal-character-names, and line splicing) are reverted; this reversion shall apply before any *d-char*, *r-char*, or delimiting parenthesis is identified. The raw string literal is defined as the shortest sequence of characters that matches the raw-string pattern

  encoding-prefix$_{opt}$`R` *raw-string*

— Otherwise, if the next three characters are `<::` and the subsequent character is neither `:` nor `>`, the `<` is treated as a preprocessor token by itself and not as the first character of the alternative token `<:`.

— Otherwise, the next preprocessing token is the longest sequence of characters that could constitute a preprocessing token, even if that would cause further lexical analysis to fail.

[*Example:*

```
#define R "x"
const char* s = R"y";           // ill-formed raw string, not "x" "y"
```

— *end example*]

1 [*Example:* The program fragment `1Ex` is parsed as a preprocessing number token (one that is not a valid floating or integer literal token), even though a parse as the pair of preprocessing tokens `1` and `Ex` might produce a valid expression (for example, if `Ex` were a macro defined as `+1`). Similarly, the program fragment `1E1` is parsed as a preprocessing number (one that is a valid floating literal token), whether or not `E` is a macro name. — *end example*]

2 [*Example:* The program fragment `x+++++y` is parsed as `x ++ ++ + y`, which, if `x` and `y` have integral types, violates a constraint on increment operators, even though the parse `x ++ + ++ y` might yield a correct expression. — *end example*]

2.236 Alternative tokens [lex.digraph]

1

Alternative token representations are provided for some operators and punctuators.[16]

1

In all respects of the language, each alternative token behaves the same, respectively, as its primary token, except for its spelling.[17] The set of alternative tokens is defined in Table 2.

Table 2 — Alternative tokens

Alternative	Primary	Alternative	Primary	Alternative	Primary
`<%`	`{`	`and`	`&&`	`and_eq`	`&=`
`%>`	`}`	`bitor`	`|`	`or_eq`	`|=`
`<:`	`[`	`or`	`||`	`xor_eq`	`^=`
`:>`	`]`	`xor`	`^`	`not`	`!`
`%:`	`#`	`compl`	`~`	`not_eq`	`!=`
`%:%:`	`##`	`bitand`	`&`		

2.247 Tokens [lex.token]

token:
- *identifier*
- *keyword*
- *literal*
- *operator*
- *punctuator*

1

There are five kinds of tokens: identifiers, keywords, literals,[18] operators, and other separators. Blanks, horizontal and vertical tabs, newlines, formfeeds, and comments (collectively, "white space"), as described below, are ignored except as they serve to separate tokens. [*Note:* Some white space is required to separate otherwise adjacent identifiers, keywords, numeric literals, and alternative tokens containing alphabetic characters. — *end note*]

2.252 Comments [lex.comment]

1

16) These include "digraphs" and additional reserved words. The term "digraph" (token consisting of two characters) is not perfectly descriptive, since one of the alternative preprocessing-tokens is `%:%:` and of course several primary tokens contain two characters. Nonetheless, those alternative tokens that aren't lexical keywords are colloquially known as "digraphs".

17) Thus the "stringized" values (16.161.1) of `[` and `<:` will be different, maintaining the source spelling, but the tokens can otherwise be freely interchanged.

18) Literals include strings and character and numeric literals.

The characters `/*` start a comment, which terminates with the characters `*/`. These comments do not nest. The characters `//` start a comment, which terminates immediately before the next new-line character. If there is a form-feed or a vertical-tab character in such a comment, only white-space characters shall appear between it and the new-line that terminates the comment; no diagnostic is required. [*Note:* The comment characters `//`, `/*`, and `*/` have no special meaning within a `//` comment and are treated just like other characters. Similarly, the comment characters `//` and `/*` have no special meaning within a `/*` comment. — *end note*]

2.257 Header names [lex.header]

header-name:
  `<` *h-char-sequence* `>`
  `"` *q-char-sequence* `"`

h-char-sequence:
  h-char
  h-char-sequence h-char

h-char:
  any member of the source character set except new-line and `>`

q-char-sequence:
  q-char
  q-char-sequence q-char

q-char:
  any member of the source character set except new-line and `"`

1

Header name preprocessing tokens shall only appear within a `#include` preprocessing directive (16.48). The sequences in both forms of *header-name*s are mapped in an implementation-defined manner to headers or to external source file names as specified in 16.48.

1

The appearance of either of the characters `'` or `\` or of either of the character sequences `/*` or `//` in a *q-char-sequence* or an *h-char-sequence* is conditionally-supported with implementation-defined semantics, as is the appearance of the character `"` in an *h-char-sequence*.[19]

2.266 Preprocessing numbers [lex.ppnumber]

pp-number:
  digit
  `.` *digit*
  pp-number digit
  pp-number identifier-nondigit
  pp-number `'` *digit*
  pp-number `'` *nondigit*
  pp-number `e` *sign*
  pp-number `E` *sign*
  pp-number `.`

1 Preprocessing number tokens lexically include all integer literal tokens (2.300.1) and all floating literal tokens (2.431.1).

2

A preprocessing number does not have a type or a value; it acquires both after a successful conversion to an integer literal token or a floating literal token.

19) Thus, a sequence of characters that resembles an escape sequence might result in an error, be interpreted as the character corresponding to the escape sequence, or have a completely different meaning, depending on the implementation.

2.268 Identifiers [lex.name]

identifier:
- *identifier-nondigit*
- *identifier identifier-nondigit*
- *identifier digit*

identifier-nondigit:
- *nondigit*
- *universal-character-name*
- other implementation-defined characters

nondigit: one of

```
a b c d e f g h i j k l m
n o p q r s t u v w x y z
A B C D E F G H I J K L M
N O P Q R S T U V W X Y Z _
```

digit: one of

```
0 1 2 3 4 5 6 7 8 9
```

1

An identifier is an arbitrarily long sequence of letters and digits. Each universal-character-name in an identifier shall designate a character whose encoding in ISO 10646 falls into one of the ranges specified in E.1. The initial element shall not be a universal-character-name designating a character whose encoding falls into one of the ranges specified in E.2. Upper- and lower-case letters are different. All characters are significant.[20]

1

The identifiers in Table 3 have a special meaning when appearing in a certain context. When referred to in the grammar, these identifiers are used explicitly rather than using the *identifier* grammar production. Unless otherwise specified, any ambiguity as to whether a given *identifier* has a special meaning is resolved to interpret the token as a regular *identifier*.

Table 3 — Identifiers with special meaning

`override`	`final`

1

In addition, some identifiers are reserved for use by C++ implementations and standard libraries (17.332.0.0.1) and shall not be used otherwise; no diagnostic is required.

2.287 Keywords [lex.key]

1

The identifiers shown in Table 4 are reserved for use as keywords (that is, they are unconditionally treated as keywords in phase 7) except in an *attribute-token* (7.1546.1) [*Note:* The `export` keyword is unused but is reserved for future use. — *end note*]:

1

Furthermore, the alternative representations shown in Table 5 for certain operators and punctuators (2.236) are reserved and shall not be used otherwise:

20) On systems in which linkers cannot accept extended characters, an encoding of the universal-character-name may be used in forming valid external identifiers. For example, some otherwise unused character or sequence of characters may be used to encode the `\u` in a universal-character-name. Extended characters may produce a long external identifier, but C++ does not place a translation limit on significant characters for external identifiers. In C++, upper- and lower-case letters are considered different for all identifiers, including external identifiers.

Table 4 — Keywords

alignas	continue	friend	register	true
alignof	decltype	goto	reinterpret_cast	try
asm	default	if	return	typedef
auto	delete	inline	short	typeid
bool	do	int	signed	typename
break	double	long	sizeof	union
case	dynamic_cast	mutable	static	unsigned
catch	else	namespace	static_assert	using
char	enum	new	static_cast	virtual
char16_t	explicit	noexcept	struct	void
char32_t	export	nullptr	switch	volatile
class	extern	operator	template	wchar_t
const	false	private	this	while
constexpr	float	protected	thread_local	
const_cast	for	public	throw	

Table 5 — Alternative representations

and	and_eq	bitand	bitor	compl	not
not_eq	or	or_eq	xor	xor_eq	

2.294 Operators and punctuators [lex.operators]

1

The lexical representation of C++ programs includes a number of preprocessing tokens which are used in the syntax of the preprocessor or are converted into tokens for operators and punctuators:

preprocessing-op-or-punc: one of

```
{     }     [     ]     #     ##    (     )
<:    :>    <%    %>    %:    %:%:  ;     :     ...
new   delete ?     ::    .     .*
+     -     *     /     %     ^     &     |     ~
!     =     <     >     +=    -=    *=    /=    %=
^=    &=    |=    <<    >>    >>=   <<=   ==    !=
<=    >=    &&    ||    ++    --    ,     ->*   ->
and   and_eq bitand bitor compl  not   not_eq
or    or_eq xor    xor_eq
```

Each *preprocessing-op-or-punc* is converted to a single token in translation phase 7 (2.6).

2.299 Literals [lex.literal]

2.299.1 Kinds of literals [lex.literal.kinds]

1

There are several kinds of literals.[21]

21) The term "literal" generally designates, in this International Standard, those tokens that are called "constants" in ISO C.

literal:
- *integer-literal*
- *character-literal*
- *floating-literal*
- *string-literal*
- *boolean-literal*
- *pointer-literal*
- *user-defined-literal*

2.300.1 Integer literals [lex.icon]

integer-literal:
- *binary-literal integer-suffix*$_{opt}$
- *octal-literal integer-suffix*$_{opt}$
- *decimal-literal integer-suffix*$_{opt}$
- *hexadecimal-literal integer-suffix*$_{opt}$

binary-literal:
- `0b` *binary-digit*
- `0B` *binary-digit*
- *binary-literal* `'`$_{opt}$ *binary-digit*

octal-literal:
- `0`
- *octal-literal* `'`$_{opt}$ *octal-digit*

decimal-literal:
- *nonzero-digit*
- *decimal-literal* `'`$_{opt}$ *digit*

hexadecimal-literal:
- `0x` *hexadecimal-digit*
- `0X` *hexadecimal-digit*
- *hexadecimal-literal* `'`$_{opt}$ *hexadecimal-digit*

binary-digit:
- `0`
- `1`

octal-digit: one of
- `0 1 2 3 4 5 6 7`

nonzero-digit: one of
- `1 2 3 4 5 6 7 8 9`

hexadecimal-digit: one of
- `0 1 2 3 4 5 6 7 8 9`
- `a b c d e f`
- `A B C D E F`

integer-suffix:
- *unsigned-suffix long-suffix*$_{opt}$
- *unsigned-suffix long-long-suffix*$_{opt}$
- *long-suffix unsigned-suffix*$_{opt}$
- *long-long-suffix unsigned-suffix*$_{opt}$

unsigned-suffix: one of
- `u U`

long-suffix: one of
- `l L`

long-long-suffix: one of
- `ll LL`

1 An *integer literal* is a sequence of digits that has no period or exponent part, with optional separating single

quotes that are ignored when determining its value. An integer literal may have a prefix that specifies its base and a suffix that specifies its type. The lexically first digit of the sequence of digits is the most significant. A *binary* integer literal (base two) begins with `0b` or `0B` and consists of a sequence of binary digits. An *octal* integer literal (base eight) begins with the digit `0` and consists of a sequence of octal digits.[22] A *decimal* integer literal (base ten) begins with a digit other than `0` and consists of a sequence of decimal digits. A *hexadecimal* integer literal (base sixteen) begins with `0x` or `0X` and consists of a sequence of hexadecimal digits, which include the decimal digits and the letters `a` through `f` and `A` through `F` with decimal values ten through fifteen. [*Example:* The number twelve can be written `12`, `014`, `0XC`, or `0b1100`. The literals `1048576`, `1'048'576`, `0X100000`, `0x10'0000`, and `0'004'000'000` all have the same value. — *end example*]

1

The type of an integer literal is the first of the corresponding list in Table 6 in which its value can be represented.

Table 6 — Types of integer literals

Suffix	Decimal literal	Binary, octal, or hexadecimal literal

none	`int`
	`long int`
	`long long int`
		`int`
		`unsigned int`
		`long int`
		`unsigned long int`
		`long long int`
		`unsigned long long int`

`u` or `U`	`unsigned int`
	`unsigned long int`
	`unsigned long long int`
		`unsigned int`
		`unsigned long int`
		`unsigned long long int`

`l` or `L`	`long int`
	`long long int`
		`long int`
		`unsigned long int`
		`long long int`
		`unsigned long long int`

Both `u` or `U` and `l` or `L`	`unsigned long int` `unsigned long long int`	`unsigned long int` `unsigned long long int`
`ll` or `LL`	`long long int`	`long long int` `unsigned long long int`
Both `u` or `U` and `ll` or `LL`	`unsigned long long int`	`unsigned long long int`

1

If an integer literal cannot be represented by any type in its list and an extended integer type (3.3151.1) can represent its value, it may have that extended integer type. If all of the types in the list for the literal are signed, the extended integer type shall be signed. If all of the types in the list for the literal are unsigned, the extended integer type shall be unsigned. If the list contains both signed and unsigned types, the extended integer type may be signed or unsigned. A program is ill-formed if one of its translation units contains an integer literal that cannot be represented by any of the allowed types.

22) The digits `8` and `9` are not octal digits.

2.356.1 Character literals [lex.ccon]

character-literal:
  ' *c-char-sequence* '
  u' *c-char-sequence* '
  U' *c-char-sequence* '
  L' *c-char-sequence* '

c-char-sequence:
  c-char
  c-char-sequence c-char

c-char:
  any member of the source character set except
    the single-quote ', backslash \, or new-line character
  escape-sequence
  universal-character-name

escape-sequence:
  simple-escape-sequence
  octal-escape-sequence
  hexadecimal-escape-sequence

simple-escape-sequence: one of
  `\'  \"  \?  \\`
  `\a  \b  \f  \n  \r  \t  \v`

octal-escape-sequence:
  \ *octal-digit*
  \ *octal-digit octal-digit*
  \ *octal-digit octal-digit octal-digit*

hexadecimal-escape-sequence:
  `\x` *hexadecimal-digit*
  hexadecimal-escape-sequence hexadecimal-digit

1

A character literal is one or more characters enclosed in single quotes, as in `'x'`, optionally preceded by one of the letters `u`, `U`, or `L`, as in `u'y'`, `U'z'`, or `L'x'`, respectively. A character literal that does not begin with `u`, `U`, or `L` is an ordinary character literal, also referred to as a narrow-character literal. An ordinary character literal that contains a single *c-char* representable in the execution character set has type `char`, with value equal to the numerical value of the encoding of the *c-char* in the execution character set. An ordinary character literal that contains more than one *c-char* is a *multicharacter literal*. A multicharacter literal, or an ordinary character literal containing a single *c-char* not representable in the execution character set, is conditionally-supported, has type `int`, and has an implementation-defined value.

1

A character literal that begins with the letter `u`, such as `u'y'`, is a character literal of type `char16_t`. The value of a `char16_t` literal containing a single *c-char* is equal to its ISO 10646 code point value, provided that the code point is representable with a single 16-bit code unit. (That is, provided it is a basic multi-lingual plane code point.) If the value is not representable within 16 bits, the program is ill-formed. A `char16_t` literal containing multiple *c-char*s is ill-formed. A character literal that begins with the letter `U`, such as `U'z'`, is a character literal of type `char32_t`. The value of a `char32_t` literal containing a single *c-char* is equal to its ISO 10646 code point value. A `char32_t` literal containing multiple *c-char*s is ill-formed. A character literal that begins with the letter `L`, such as `L'x'`, is a wide-character literal. A wide-character literal has type `wchar_t`.[23] The value of a wide-character literal containing a single *c-char* has value equal to the numerical value of the encoding of the *c-char* in the execution wide-character set, unless the *c-char* has no representation in the execution wide-character set, in which case the value is implementation-defined.

23) They are intended for character sets where a character does not fit into a single byte.

[*Note:* The type `wchar_t` is able to represent all members of the execution wide-character set (see 3.3151.1). — *end note*]. The value of a wide-character literal containing multiple *c-char*s is implementation-defined.

1

Certain nongraphic characters, the single quote `'`, the double quote `"`, the question mark `?`,[24] and the backslash `\`, can be represented according to Table 7. The double quote `"` and the question mark `?`, can be represented as themselves or by the escape sequences `\"` and `\?` respectively, but the single quote `'` and the backslash `\` shall be represented by the escape sequences `\'` and `\\` respectively. Escape sequences in which the character following the backslash is not listed in Table 7 are conditionally-supported, with implementation-defined semantics. An escape sequence specifies a single character.

Table 7 — Escape sequences

new-line	NL(LF)	`\n`
horizontal tab	HT	`\t`
vertical tab	VT	`\v`
backspace	BS	`\b`
carriage return	CR	`\r`
form feed	FF	`\f`
alert	BEL	`\a`
backslash	\	`\\`
question mark	?	`\?`
single quote	'	`\'`
double quote	"	`\"`
octal number	*ooo*	`\`*ooo*
hex number	*hhh*	`\x`*hhh*

1

The escape `\`*ooo* consists of the backslash followed by one, two, or three octal digits that are taken to specify the value of the desired character. The escape `\x`*hhh* consists of the backslash followed by `x` followed by one or more hexadecimal digits that are taken to specify the value of the desired character. There is no limit to the number of digits in a hexadecimal sequence. A sequence of octal or hexadecimal digits is terminated by the first character that is not an octal digit or a hexadecimal digit, respectively. The value of a character literal is implementation-defined if it falls outside of the implementation-defined range defined for `char` (for literals with no prefix), `char16_t` (for literals prefixed by `'u'`), `char32_t` (for literals prefixed by `'U'`), or `wchar_t` (for literals prefixed by `'L'`).

1

A universal-character-name is translated to the encoding, in the appropriate execution character set, of the character named. If there is no such encoding, the universal-character-name is translated to an implementation-defined encoding. [*Note:* In translation phase 1, a universal-character-name is introduced whenever an actual extended character is encountered in the source text. Therefore, all extended characters are described in terms of universal-character-names. However, the actual compiler implementation may use its own native character set, so long as the same results are obtained. — *end note*]

2.431.1 Floating literals [lex.fcon]

floating-literal:
  fractional-constant exponent-part$_{opt}$ *floating-suffix*$_{opt}$
  digit-sequence exponent-part floating-suffix$_{opt}$

24) Using an escape sequence for a question mark can avoid accidentally creating a trigraph.

fractional-constant:
  digit-sequence$_{opt}$ `.` *digit-sequence*
  digit-sequence `.`
exponent-part:
  `e` *sign*$_{opt}$ *digit-sequence*
  `E` *sign*$_{opt}$ *digit-sequence*
sign: one of
  `+ -`
digit-sequence:
  digit
  digit-sequence `'`$_{opt}$ *digit*
floating-suffix: one of
  `f l F L`

1

A floating literal consists of an integer part, a decimal point, a fraction part, an `e` or `E`, an optionally signed integer exponent, and an optional type suffix. The integer and fraction parts both consist of a sequence of decimal (base ten) digits. Optional separating single quotes in a *digit-sequence* are ignored when determining its value. [*Example:* The literals `1.602'176'565e-19` and `1.602176565e-19` have the same value. — *end example*] Either the integer part or the fraction part (not both) can be omitted; either the decimal point or the letter `e` (or `E`) and the exponent (not both) can be omitted. The integer part, the optional decimal point and the optional fraction part form the *significant part* of the floating literal. The exponent, if present, indicates the power of 10 by which the significant part is to be scaled. If the scaled value is in the range of representable values for its type, the result is the scaled value if representable, else the larger or smaller representable value nearest the scaled value, chosen in an implementation-defined manner. The type of a floating literal is `double` unless explicitly specified by a suffix. The suffixes `f` and `F` specify `float`, the suffixes `l` and `L` specify `long double`. If the scaled value is not in the range of representable values for its type, the program is ill-formed.

2.453.1 String literals [lex.string]

string-literal:
  encoding-prefix$_{opt}$`"` *s-char-sequence*$_{opt}$`"`
  encoding-prefix$_{opt}$`R` *raw-string*
encoding-prefix:
  `u8`
  `u`
  `U`
  `L`
s-char-sequence:
  s-char
  s-char-sequence s-char
s-char:
  any member of the source character set except
    the double-quote `"`, backslash `\`, or new-line character
  escape-sequence
  universal-character-name
raw-string:
  `"` *d-char-sequence*$_{opt}$`(` *r-char-sequence*$_{opt}$`)` *d-char-sequence*$_{opt}$`"`
r-char-sequence:
  r-char
  r-char-sequence r-char

r-char:
any member of the source character set, except
a right parenthesis `)` followed by the initial *d-char-sequence*
(which may be empty) followed by a double quote `"`.

d-char-sequence:
d-char
d-char-sequence d-char

d-char:
any member of the basic source character set except:
space, the left parenthesis `(`, the right parenthesis `)`, the backslash `\`,
and the control characters representing horizontal tab,
vertical tab, form feed, and newline.

1

A string literal is a sequence of characters (as defined in 2.356.1) surrounded by double quotes, optionally prefixed by `R`, `u8`, `u8R`, `u`, `uR`, `U`, `UR`, `L`, or `LR`, as in `"..."`, `R"(...)"`, `u8"..."`, `u8R"**(...)**"`, `u"..."`, `uR"*~(...)*~"`, `U"..."`, `UR"zzz(...)zzz"`, `L"..."`, or `LR"(...)"`, respectively.

1

A string literal that has an `R` in the prefix is a *raw string literal*. The *d-char-sequence* serves as a delimiter. The terminating *d-char-sequence* of a *raw-string* is the same sequence of characters as the initial *d-char-sequence*. A *d-char-sequence* shall consist of at most 16 characters.

1 [*Note:* The characters `'('` and `')'` are permitted in a *raw-string*. Thus, `R"delimiter((a|b))delimiter"` is equivalent to `"(a|b)"`. — *end note*]

2

[*Note:* A source-file new-line in a raw string literal results in a new-line in the resulting execution *string-literal*. Assuming no whitespace at the beginning of lines in the following example, the assert will succeed:

```
const char* p = R"(a\
b
c)";
assert(std::strcmp(p, "a\\\nb\nc") == 0);
```

— *end note*]

1 [*Example:* The raw string

```
R"a(
)\
a"
)a"
```

is equivalent to `"\n)\\\na\"\n"`. The raw string

```
R"(??)"
```

is equivalent to `"\?\?"`. The raw string

```
R"#(
)??="
)#"
```

is equivalent to `"\n)\?\?=\"\n"`. — *end example*]

2

After translation phase 6, a string literal that does not begin with an *encoding-prefix* is an ordinary string literal, and is initialized with the given characters.

1 A string literal that begins with `u8`, such as `u8"asdf"`, is a UTF-8 string literal.

2

Ordinary string literals and UTF-8 string literals are also referred to as narrow string literals. A narrow string literal has type "array of n `const char`", where n is the size of the string as defined below, and has static storage duration (3.2235).

1 For a UTF-8 string literal, each successive element of the object representation (3.2955) has the value of the corresponding code unit of the UTF-8 encoding of the string.

2

A string literal that begins with `u`, such as `u"asdf"`, is a `char16_t` string literal. A `char16_t` string literal has type "array of n `const char16_t`", where n is the size of the string as defined below; it has static storage duration and is initialized with the given characters. A single *c-char* may produce more than one `char16_t` character in the form of surrogate pairs.

1 A string literal that begins with `U`, such as `U"asdf"`, is a `char32_t` string literal. A `char32_t` string literal has type "array of n `const char32_t`", where n is the size of the string as defined below; it has static storage duration and is initialized with the given characters.

2

A string literal that begins with `L`, such as `L"asdf"`, is a wide string literal. A wide string literal has type "array of n `const wchar_t`", where n is the size of the string as defined below; it has static storage duration and is initialized with the given characters.

1

Whether all string literals are distinct (that is, are stored in nonoverlapping objects) is implementation-defined. The effect of attempting to modify a string literal is undefined.

1

In translation phase 6 (2.6), adjacent string literals are concatenated. If both string literals have the same *encoding-prefix*, the resulting concatenated string literal has that *encoding-prefix*. If one string literal has no *encoding-prefix*, it is treated as a string literal of the same *encoding-prefix* as the other operand. If a UTF-8 string literal token is adjacent to a wide string literal token, the program is ill-formed. Any other concatenations are conditionally-supported with implementation-defined behavior. [*Note:* This concatenation is an interpretation, not a conversion. Because the interpretation happens in translation phase 6 (after each character from a literal has been translated into a value from the appropriate character set), a string literal's initial rawness has no effect on the interpretation or well-formedness of the concatenation. — *end note*] Table 8 has some examples of valid concatenations.

Table 8 — String literal concatenations

Source		Means	Source		Means	Source		Means
`u"a"`	`u"b"`	`u"ab"`	`U"a"`	`U"b"`	`U"ab"`	`L"a"`	`L"b"`	`L"ab"`
`u"a"`	`"b"`	`u"ab"`	`U"a"`	`"b"`	`U"ab"`	`L"a"`	`"b"`	`L"ab"`
`"a"`	`u"b"`	`u"ab"`	`"a"`	`U"b"`	`U"ab"`	`"a"`	`L"b"`	`L"ab"`

Characters in concatenated strings are kept distinct.

[*Example:*

```
"\xA" "B"
```

contains the two characters `'\xA'` and `'B'` after concatenation (and not the single hexadecimal character `'\xAB'`). — *end example*]

1

After any necessary concatenation, in translation phase 7 (2.6), `'\0'` is appended to every string literal so that programs that scan a string can find its end.

1

Escape sequences and universal-character-names in non-raw string literals have the same meaning as in character literals (2.356.1), except that the single quote `'` is representable either by itself or by the escape sequence `\'`, and the double quote `"` shall be preceded by a `\`. In a narrow string literal, a universal-character-name may map to more than one `char` element due to *multibyte encoding*. The size of a `char32_t` or wide string literal is the total number of escape sequences, universal-character-names, and other characters, plus one for the terminating `U'\0'` or `L'\0'`. The size of a `char16_t` string literal is the total number of escape sequences, universal-character-names, and other characters, plus one for each character requiring a surrogate pair, plus one for the terminating `u'\0'`. [*Note:* The size of a `char16_t` string literal is the number of code units, not the number of characters. — *end note*] Within `char32_t` and `char16_t` literals, any universal-character-names shall be within the range `0x0` to `0x10FFFF`. The size of a narrow string literal is the total number of escape sequences and other characters, plus at least one for the multibyte encoding of each universal-character-name, plus one for the terminating `'\0'`.

2.605.1 Boolean literals [lex.bool]

boolean-literal:
`false`
`true`

1

The Boolean literals are the keywords `false` and `true`. Such literals are prvalues and have type `bool`.

2.607.1 Pointer literals [lex.nullptr]

pointer-literal:
`nullptr`

1

The pointer literal is the keyword `nullptr`. It is a prvalue of type `std::nullptr_t`. [*Note:* `std::nullptr_t` is a distinct type that is neither a pointer type nor a pointer to member type; rather, a prvalue of this type is a null pointer constant and can be converted to a null pointer value or null member pointer value. See 4.579 and 4.710. — *end note*]

2.622.1 User-defined literals [lex.ext]

user-defined-literal:
user-defined-integer-literal
user-defined-floating-literal
user-defined-string-literal
user-defined-character-literal

user-defined-integer-literal:
decimal-literal ud-suffix
octal-literal ud-suffix
hexadecimal-literal ud-suffix
binary-literal ud-suffix

user-defined-floating-literal:
fractional-constant exponent-part$_{opt}$ *ud-suffix*
digit-sequence exponent-part ud-suffix

user-defined-string-literal:
string-literal ud-suffix
user-defined-character-literal:
character-literal ud-suffix
ud-suffix:
identifier

1

If a token matches both *user-defined-literal* and another literal kind, it is treated as the latter. [*Example:* `123_km` is a *user-defined-literal*, but `12LL` is an *integer-literal*. — *end example*] The syntactic non-terminal preceding the *ud-suffix* in a *user-defined-literal* is taken to be the longest sequence of characters that could match that non-terminal.

1

A *user-defined-literal* is treated as a call to a literal operator or literal operator template (13.1241.1). To determine the form of this call for a given *user-defined-literal* L with *ud-suffix* X, the *literal-operator-id* whose literal suffix identifier is X is looked up in the context of L using the rules for unqualified name lookup (3.952.1). Let S be the set of declarations found by this lookup. S shall not be empty.

1

If L is a *user-defined-integer-literal*, let n be the literal without its *ud-suffix*. If S contains a literal operator with parameter type `unsigned long long`, the literal L is treated as a call of the form

```
operator "" X(nULL)
```

Otherwise, S shall contain a raw literal operator or a literal operator template (13.1241.1) but not both. If S contains a raw literal operator, the literal L is treated as a call of the form

```
operator "" X("n")
```

Otherwise (S contains a literal operator template), L is treated as a call of the form

```
operator "" X<'c1', 'c2', ... 'ck'>()
```

where n is the source character sequence $c_1c_2...c_k$. [*Note:* The sequence $c_1c_2...c_k$ can only contain characters from the basic source character set. — *end note*]

1 If L is a *user-defined-floating-literal*, let f be the literal without its *ud-suffix*. If S contains a literal operator with parameter type `long double`, the literal L is treated as a call of the form

```
operator "" X(fL)
```

Otherwise, S shall contain a raw literal operator or a literal operator template (13.1241.1) but not both. If S contains a raw literal operator, the *literal* L is treated as a call of the form

```
operator "" X("f")
```

Otherwise (S contains a literal operator template), L is treated as a call of the form

```
operator "" X<'c1', 'c2', ... 'ck'>()
```

where f is the source character sequence $c_1c_2...c_k$. [*Note:* The sequence $c_1c_2...c_k$ can only contain characters from the basic source character set. — *end note*]

2

If L is a *user-defined-string-literal*, let *str* be the literal without its *ud-suffix* and let *len* be the number of code units in *str* (i.e., its length excluding the terminating null character). The literal L is treated as a call of the form

```
operator "" X(str, len)
```

1 If L is a *user-defined-character-literal*, let *ch* be the literal without its *ud-suffix*. S shall contain a literal operator (13.1241.1) whose only parameter has the type of *ch* and the literal L is treated as a call of the form

```
operator "" X(ch)
```

2 [*Example:*

```
long double operator "" _w(long double);
std::string operator "" _w(const char16_t*, std::size_t);
unsigned operator "" _w(const char*);
int main() {
  1.2_w;      // calls operator "" _w(1.2L)
  u"one"_w;   // calls operator "" _w(u"one", 3)
  12_w;       // calls operator "" _w("12")
  "two"_w;    // error: no applicable literal operator
}
```

— *end example*]

3 In translation phase 6 (2.6), adjacent string literals are concatenated and *user-defined-string-literal*s are considered string literals for that purpose. During concatenation, *ud-suffix*es are removed and ignored and the concatenation process occurs as described in 2.453.1. At the end of phase 6, if a string literal is the result of a concatenation involving at least one *user-defined-string-literal*, all the participating *user-defined-string-literal*s shall have the same *ud-suffix* and that suffix is applied to the result of the concatenation.

4 [*Example:*

```
int main() {
  L"A" "B" "C"_x; // OK: same as L"ABC"_x
  "P"_x "Q" "R"_y;// error: two different ud-suffixes
}
```

— *end example*]

5 Some *identifier*s appearing as *ud-suffix*es are reserved for future standardization (17.424.0.0.1). A program containing such a *ud-suffix* is ill-formed, no diagnostic required.

3 Basic concepts [basic]

1 [*Note:* This Clause presents the basic concepts of the C++ language. It explains the difference between an *object* and a *name* and how they relate to the value categories for expressions. It introduces the concepts of a *declaration* and a *definition* and presents C++'s notion of *type*, *scope*, *linkage*, and *storage duration*. The mechanisms for starting and terminating a program are discussed. Finally, this Clause presents the *fundamental* types of the language and lists the ways of constructing *compound* types from these. — *end note*]

2 [*Note:* This Clause does not cover concepts that affect only a single part of the language. Such concepts are discussed in the relevant Clauses. — *end note*]

3

An *entity* is a value, object, reference, function, enumerator, type, class member, template, template specialization, namespace, parameter pack, or `this`.

1

A *name* is a use of an *identifier* (2.268), *operator-function-id* (13.1122), *literal-operator-id* (13.1241.1), *conversion-function-id* (12.742.1), or *template-id* (14.224) that denotes an entity or *label* (6.413.1, 6.3).

1

Every name that denotes an entity is introduced by a *declaration*. Every name that denotes a label is introduced either by a `goto` statement (6.413.1) or a *labeled-statement* (6.3).

1

A *variable* is introduced by the declaration of a reference other than a non-static data member or of an object. The variable's name, if any, denotes the reference or object.

1

Some names denote types or templates. In general, whenever a name is encountered it is necessary to determine whether that name denotes one of these entities before continuing to parse the program that contains it. The process that determines this is called *name lookup* (3.923).

1

Two names are *the same* if

— they are *identifier*s composed of the same character sequence, or

— they are *operator-function-id*s formed with the same operator, or

— they are *conversion-function-id*s formed with the same type, or

— they are *template-id*s that refer to the same class, function, or variable (14.595), or

— they are the names of literal operators (13.1241.1) formed with the same literal suffix identifier.

1

A name used in more than one translation unit can potentially refer to the same entity in these translation units depending on the linkage (3.1459) of the name specified in each translation unit.

3.43 Declarations and definitions [basic.def]

1

A declaration (Clause 7) may introduce one or more names into a translation unit or redeclare names introduced by previous declarations. If so, the declaration specifies the interpretation and attributes of these names. A declaration may also have effects including:

— a static assertion (Clause 7),

— controlling template instantiation (14.1841.1),

— use of attributes (Clause 7), and

— nothing (in the case of an *empty-declaration*).

1

A declaration is a *definition* unless it declares a function without specifying the function's body (8.706), it contains the `extern` specifier (7.49.1) or a *linkage-specification*[25] (7.1477) and neither an *initializer* nor a *function-body*, it declares a static data member in a class definition (9.194, 9.559), it is a class name declaration (9.172), it is an *opaque-enum-declaration* (7.1001), it is a *template-parameter* (14.97), it is a *parameter-declaration* (8.360.1) in a function declarator that is not the *declarator* of a *function-definition*, or it is a `typedef` declaration (7.235.1), an *alias-declaration* (7.235.1), a *using-declaration* (7.1311.1), a *static_assert-declaration* (Clause 7), an *attribute-declaration* (Clause 7), an *empty-declaration* (Clause 7), or a *using-directive* (7.1416.1).

[*Example:* all but one of the following are definitions:

```
int a;                          // defines a
extern const int c = 1;         // defines c
int f(int x) { return x+a; }    // defines f and defines x
struct S { int a; int b; };     // defines S, S::a, and S::b
struct X {                      // defines X
  int x;                        // defines non-static data member x
  static int y;                 // declares static data member y
  X(): x(0) { }                 // defines a constructor of X
};
int X::y = 1;                   // defines X::y
enum { up, down };              // defines up and down
namespace N { int d; }          // defines N and N::d
namespace N1 = N;               // defines N1
X anX;                          // defines anX
```

whereas these are just declarations:

```
extern int a;                   // declares a
extern const int c;             // declares c
int f(int);                     // declares f
struct S;                       // declares S
typedef int Int;                // declares Int
extern X anotherX;              // declares anotherX
using N::d;                     // declares d
```

— *end example*]

1

25) Appearing inside the braced-enclosed *declaration-seq* in a *linkage-specification* does not affect whether a declaration is a definition.

[*Note:* In some circumstances, C++ implementations implicitly define the default constructor (12.30), copy constructor (12.1577), move constructor (12.1577), copy assignment operator (12.1577), move assignment operator (12.1577), or destructor (12.807) member functions. — *end note*] [*Example:* given

```
#include <string>

struct C {
  std::string s;              // std::string is the standard library class (Clause 21)
};

int main() {
  C a;
  C b = a;
  b = a;
}
```

the implementation will implicitly define functions to make the definition of `C` equivalent to

```
struct C {
  std::string s;
  C() : s() { }
  C(const C& x): s(x.s) { }
  C(C&& x): s(static_cast<std::string&&>(x.s)) { }
    // :  s(std::move(x.s)) { }
  C& operator=(const C& x) { s = x.s; return *this; }
  C& operator=(C&& x) { s = static_cast<std::string&&>(x.s); return *this; }
    // { s = std::move(x.s); return *this; }
  ~C() { }
};
```

— *end example*]

1

[*Note:* A class name can also be implicitly declared by an *elaborated-type-specifier* (7.808.0.1). — *end note*]

1

A program is ill-formed if the definition of any object gives the object an incomplete type (3.2955).

3.91 One definition rule [basic.def.odr]

1

No translation unit shall contain more than one definition of any variable, function, class type, enumeration type, or template.

1

An expression is *potentially evaluated* unless it is an unevaluated operand (Clause 5) or a subexpression thereof. The set of *potential results* of an expression `e` is defined as follows:

— If `e` is an *id-expression* (5.398.1), the set contains only `e`.

— If `e` is a class member access expression (5.1194.1), the set contains the potential results of the object expression.

— If `e` is a pointer-to-member expression (5.2832) whose second operand is a constant expression, the set contains the potential results of the object expression.

— If `e` has the form `(e1)`, the set contains the potential results of `e1`.

— If `e` is a glvalue conditional expression (5.3337), the set is the union of the sets of potential results of the second and third operands.

— If `e` is a comma expression (5.3602), the set contains the potential results of the right operand.

— Otherwise, the set is empty.

[*Note:* This set is a (possibly-empty) set of *id-expressions*, each of which is either `e` or a subexpression of `e`. [*Example:* In the following example, the set of potential results of the initializer of `n` contains the first `S::x` subexpression, but not the second `S::x` subexpression.

```
struct S { static const int x = 0; };
const int &f(const int &r);
int n = b ? (1, S::x)  // S::x is not odr-used here
          : f(S::x);   // S::x is odr-used here, so
                       // a definition is required
```

— *end example*] — *end note*]

1

A variable `x` whose name appears as a potentially-evaluated expression `ex` is *odr-used* by `ex` unless applying the lvalue-to-rvalue conversion (4.127) to `x` yields a constant expression (5.3643) that does not invoke any non-trivial functions and, if `x` is an object, `ex` is an element of the set of potential results of an expression `e`, where either the lvalue-to-rvalue conversion (4.127) is applied to `e`, or `e` is a discarded-value expression (Clause 5). `this` is odr-used if it appears as a potentially-evaluated expression (including as the result of the implicit transformation in the body of a non-static member function (9.465.1)). A virtual member function is odr-used if it is not pure. A function whose name appears as a potentially-evaluated expression is odr-used if it is the unique lookup result or the selected member of a set of overloaded functions (3.923, 13.88, 13.1084), unless it is a pure virtual function and its name is not explicitly qualified. [*Note:* This covers calls to named functions (5.955.1), operator overloading (Clause 13), user-defined conversions (12.742.1), allocation function for placement new (5.2221.1), as well as non-default initialization (8.821). A constructor selected to copy or move an object of class type is odr-used even if the call is actually elided by the implementation (12.1577). — *end note*] An allocation or deallocation function for a class is odr-used by a new expression appearing in a potentially-evaluated expression as specified in 5.2221.1 and 12.988. A deallocation function for a class is odr-used by a delete expression appearing in a potentially-evaluated expression as specified in 5.2455.1 and 12.988. A non-placement allocation or deallocation function for a class is odr-used by the definition of a constructor of that class. A non-placement deallocation function for a class is odr-used by the definition of the destructor of that class, or by being selected by the lookup at the point of definition of a virtual destructor (12.807).[26] An assignment operator function in a class is odr-used by an implicitly-defined copy-assignment or move-assignment function for another class as specified in 12.1577. A default constructor for a class is odr-used by default initialization or value initialization as specified in 8.821. A constructor for a class is odr-used as specified in 8.821. A destructor for a class is odr-used if it is potentially invoked (12.807).

1

Every program shall contain exactly one definition of every non-inline function or variable that is odr-used in that program; no diagnostic required. The definition can appear explicitly in the program, it can be found in the standard or a user-defined library, or (when appropriate) it is implicitly defined (see 12.30, 12.807 and 12.1577). An inline function shall be defined in every translation unit in which it is odr-used.

1

26) An implementation is not required to call allocation and deallocation functions from constructors or destructors; however, this is a permissible implementation technique.

Exactly one definition of a class is required in a translation unit if the class is used in a way that requires the class type to be complete. [*Example:* the following complete translation unit is well-formed, even though it never defines `X`:

```
struct X;                    // declare X as a struct type
struct X* x1;                // use X in pointer formation
X* x2;                       // use X in pointer formation
```

— *end example*] [*Note:* The rules for declarations and expressions describe in which contexts complete class types are required. A class type `T` must be complete if:

— an object of type `T` is defined (3.43), or

— a non-static class data member of type `T` is declared (9.194), or

— `T` is used as the object type or array element type in a *new-expression* (5.2221.1), or

— an lvalue-to-rvalue conversion is applied to a glvalue referring to an object of type `T` (4.127), or

— an expression is converted (either implicitly or explicitly) to type `T` (Clause 4, 5.1108.1, 5.1295.1, 5.1443.1, 5.2765), or

— an expression that is not a null pointer constant, and has type other than *cv* `void*`, is converted to the type pointer to `T` or reference to `T` using a standard conversion (Clause 4), a `dynamic_cast` (5.1295.1) or a `static_cast` (5.1443.1), or

— a class member access operator is applied to an expression of type `T` (5.1194.1), or

— the `typeid` operator (5.1393.1) or the `sizeof` operator (5.2075.1) is applied to an operand of type `T`, or

— a function with a return type or argument type of type `T` is defined (3.43) or called (5.955.1), or

— a class with a base class of type `T` is defined (Clause 10), or

— an lvalue of type `T` is assigned to (5.3483), or

— the type `T` is the subject of an `alignof` expression (5.2747.1), or

— an *exception-declaration* has type `T`, reference to `T`, or pointer to `T` (15.146).

— *end note*]

1

There can be more than one definition of a class type (Clause 9), enumeration type (7.1001), inline function with external linkage (7.94.1), class template (Clause 14), non-static function template (14.972.1), static data member of a class template (14.634.0.1), member function of a class template (14.630.0.1), or template specialization for which some template parameters are not specified (14.1614, 14.812.1) in a program provided that each definition appears in a different translation unit, and provided the definitions satisfy the following requirements. Given such an entity named `D` defined in more than one translation unit, then

— each definition of `D` shall consist of the same sequence of tokens; and

— in each definition of D, corresponding names, looked up according to 3.923, shall refer to an entity defined within the definition of D, or shall refer to the same entity, after overload resolution (13.88) and after matching of partial template specialization (14.2662.1), except that a name can refer to a non-volatile const object with internal or no linkage if the object has the same literal type in all definitions of D, and the object is initialized with a constant expression (5.3643), and the object is not odr-used, and the object has the same value in all definitions of D; and

— in each definition of D, corresponding entities shall have the same language linkage; and

— in each definition of D, the overloaded operators referred to, the implicit calls to conversion functions, constructors, operator new functions and operator delete functions, shall refer to the same function, or to a function defined within the definition of D; and

— in each definition of D, a default argument used by an (implicit or explicit) function call is treated as if its token sequence were present in the definition of D; that is, the default argument is subject to the three requirements described above (and, if the default argument has sub-expressions with default arguments, this requirement applies recursively).[27]

— if D is a class with an implicitly-declared constructor (12.30), it is as if the constructor was implicitly defined in every translation unit where it is odr-used, and the implicit definition in every translation unit shall call the same constructor for a base class or a class member of D. [*Example:*

```
//translation unit 1:
struct X {
  X(int);
  X(int, int);
};
X::X(int = 0) { }
class D: public X { };
D d2;                          // X(int) called by D()

//translation unit 2:
struct X {
  X(int);
  X(int, int);
};
X::X(int = 0, int = 0) { }
class D: public X { };         // X(int, int) called by D();
                               // D()'s implicit definition
                               // violates the ODR
```

— *end example*]

If D is a template and is defined in more than one translation unit, then the preceding requirements shall apply both to names from the template's enclosing scope used in the template definition (14.1444.1), and also to dependent names at the point of instantiation (14.1257.1). If the definitions of D satisfy all these requirements, then the behavior is as if there were a single definition of D. If the definitions of D do not satisfy these requirements, then the behavior is undefined.

3.464 Scope [basic.scope]

3.464.1 Declarative regions and scopes [basic.scope.declarative]

1

27) 8.545.1 describes how default argument names are looked up.

Every name is introduced in some portion of program text called a *declarative region*, which is the largest part of the program in which that name is *valid*, that is, in which that name may be used as an unqualified name to refer to the same entity. In general, each particular name is valid only within some possibly discontiguous portion of program text called its *scope*. To determine the scope of a declaration, it is sometimes convenient to refer to the *potential scope* of a declaration. The scope of a declaration is the same as its potential scope unless the potential scope contains another declaration of the same name. In that case, the potential scope of the declaration in the inner (contained) declarative region is excluded from the scope of the declaration in the outer (containing) declarative region.

1

[*Example:* in

```
int j = 24;
int main() {
  int i = j, j;
  j = 42;
}
```

the identifier `j` is declared twice as a name (and used twice). The declarative region of the first `j` includes the entire example. The potential scope of the first `j` begins immediately after that `j` and extends to the end of the program, but its (actual) scope excludes the text between the `,` and the `}`. The declarative region of the second declaration of `j` (the `j` immediately before the semicolon) includes all the text between `{` and `}`, but its potential scope excludes the declaration of `i`. The scope of the second declaration of `j` is the same as its potential scope. — *end example*]

1

The names declared by a declaration are introduced into the scope in which the declaration occurs, except that the presence of a `friend` specifier (11.94), certain uses of the *elaborated-type-specifier* (7.808.0.1), and *using-directives* (7.1416.1) alter this general behavior.

1

Given a set of declarations in a single declarative region, each of which specifies the same unqualified name,

— they shall all refer to the same entity, or all refer to functions and function templates; or

— exactly one declaration shall declare a class name or enumeration name that is not a typedef name and the other declarations shall all refer to the same variable or enumerator, or all refer to functions and function templates; in this case the class name or enumeration name is hidden (3.875.1). [*Note:* A namespace name or a class template name must be unique in its declarative region (7.1306.1, Clause 14). — *end note*]

[*Note:* These restrictions apply to the declarative region into which a name is introduced, which is not necessarily the same as the region in which the declaration occurs. In particular, *elaborated-type-specifiers* (7.808.0.1) and friend declarations (11.94) may introduce a (possibly not visible) name into an enclosing namespace; these restrictions apply to that region. Local extern declarations (3.1459) may introduce a name into the declarative region where the declaration appears and also introduce a (possibly not visible) name into an enclosing namespace; these restrictions apply to both regions. — *end note*]

1 [*Note:* The name lookup rules are summarized in 3.923. — *end note*]

3.536.1 Point of declaration [basic.scope.pdecl]

1

The *point of declaration* for a name is immediately after its complete declarator (Clause 8) and before its *initializer* (if any), except as noted below. [*Example:*

```
unsigned char x = 12;
{ unsigned char x = x; }
```

Here the second `x` is initialized with its own (indeterminate) value. — *end example*]

1

[*Note:* a name from an outer scope remains visible up to the point of declaration of the name that hides it.[*Example:*

```
const int  i = 2;
{ int  i[i]; }
```

declares a block-scope array of two integers. — *end example*] — *end note*]

1

The point of declaration for a class or class template first declared by a *class-specifier* is immediately after the *identifier* or *simple-template-id* (if any) in its *class-head* (Clause 9). The point of declaration for an enumeration is immediately after the *identifier* (if any) in either its *enum-specifier* (7.1001) or its first *opaque-enum-declaration* (7.1001), whichever comes first. The point of declaration of an alias or alias template immediately follows the *type-id* to which the alias refers.

1 The point of declaration of a *using-declaration* that does not name a constructor is immediately after the *using-declaration* (7.1311.1).

2

The point of declaration for an enumerator is immediately after its *enumerator-definition*.[*Example:*

```
const int x = 12;
{ enum { x = x }; }
```

Here, the enumerator `x` is initialized with the value of the constant `x`, namely 12. — *end example*]

1

After the point of declaration of a class member, the member name can be looked up in the scope of its class. [*Note:* this is true even if the class is an incomplete class. For example,

```
struct X {
  enum E { z = 16 };
  int b[X::z];      // OK
};
```

— *end note*]

1

The point of declaration of a class first declared in an *elaborated-type-specifier* is as follows:

— for a declaration of the form

class-key attribute-specifier-seq$_{opt}$ *identifier* ;

the *identifier* is declared to be a *class-name* in the scope that contains the declaration, otherwise

— for an *elaborated-type-specifier* of the form

class-key identifier

if the *elaborated-type-specifier* is used in the *decl-specifier-seq* or *parameter-declaration-clause* of a function defined in namespace scope, the *identifier* is declared as a *class-name* in the namespace that contains the declaration; otherwise, except as a friend declaration, the *identifier* is declared in the

smallest namespace or block scope that contains the declaration. [*Note:* These rules also apply within templates. — *end note*] [*Note:* Other forms of *elaborated-type-specifier* do not declare a new name, and therefore must refer to an existing *type-name*. See 3.1395.1 and 7.808.0.1. — *end note*]

1

The point of declaration for an *injected-class-name* (Clause 9) is immediately following the opening brace of the class definition.

1 The point of declaration for a function-local predefined variable (8.706) is immediately before the *function-body* of a function definition.

2 The point of declaration for a template parameter is immediately after its complete *template-parameter*. [*Example:*

```
typedef unsigned char T;
template<class T
  = T      // lookup finds the typedef name of unsigned char
  , T      // lookup finds the template parameter
    N = 0> struct A { };
```

— *end example*]

3

[*Note:* Friend declarations refer to functions or classes that are members of the nearest enclosing namespace, but they do not introduce new names into that namespace (7.1215.0.1). Function declarations at block scope and variable declarations with the `extern` specifier at block scope refer to declarations that are members of an enclosing namespace, but they do not introduce new names into that scope. — *end note*]

1 [*Note:* For point of instantiation of a template, see 14.1486.0.1. — *end note*]

3.694.1 Block scope [basic.scope.block]

1

A name declared in a block (6.15) is local to that block; it has *block scope*. Its potential scope begins at its point of declaration (3.536.1) and ends at the end of its block. A variable declared at block scope is a *local variable*.

1

The potential scope of a function parameter name (including one appearing in a *lambda-declarator*) or of a function-local predefined variable in a function definition (8.706) begins at its point of declaration. If the function has a *function-try-block* the potential scope of a parameter or of a function-local predefined variable ends at the end of the last associated handler, otherwise it ends at the end of the outermost block of the function definition. A parameter name shall not be redeclared in the outermost block of the function definition nor in the outermost block of any handler associated with a *function-try-block*.

1

The name declared in an *exception-declaration* is local to the *handler* and shall not be redeclared in the outermost block of the *handler*.

1

Names declared in the *for-init-statement*, the *for-range-declaration*, and in the *condition* of `if`, `while`, `for`, and `switch` statements are local to the `if`, `while`, `for`, or `switch` statement (including the controlled statement), and shall not be redeclared in a subsequent condition of that statement nor in the outermost block (or, for the `if` statement, any of the outermost blocks) of the controlled statement; see 6.23.

3.729.1 Function prototype scope [basic.scope.proto]

1

In a function declaration, or in any function declarator except the declarator of a function definition (8.706), names of parameters (if supplied) have function prototype scope, which terminates at the end of the nearest enclosing function declarator.

3.735.1 Function scope [basic.funscope]

1

Labels (6.3) have *function scope* and may be used anywhere in the function in which they are declared. Only labels have function scope.

3.736.1 Namespace scope [basic.scope.namespace]

1

The declarative region of a *namespace-definition* is its *namespace-body*. The potential scope denoted by an *original-namespace-name* is the concatenation of the declarative regions established by each of the *namespace-definition*s in the same declarative region with that *original-namespace-name*. Entities declared in a *namespace-body* are said to be *members* of the namespace, and names introduced by these declarations into the declarative region of the namespace are said to be *member names* of the namespace. A namespace member name has namespace scope. Its potential scope includes its namespace from the name's point of declaration (3.536.1) onwards; and for each *using-directive* (7.1416.1) that nominates the member's namespace, the member's potential scope includes that portion of the potential scope of the *using-directive* that follows the member's point of declaration. [*Example:*

```
namespace N {
  int i;
  int g(int a) { return a; }
  int j();
  void q();
}
namespace { int l=1; }
// the potential scope of l is from its point of declaration
// to the end of the translation unit

namespace N {
  int g(char a) {   // overloads N::g(int)
    return l+a;     // l is from unnamed namespace
  }

  int i;            // error: duplicate definition
  int j();          // OK: duplicate function declaration

  int j() {         // OK: definition of N::j()
    return g(i);    // calls N::g(int)
  }
  int q();          // error: different return type
}
```

— *end example*]

1

A namespace member can also be referred to after the `::` scope resolution operator (5.398) applied to the name of its namespace or the name of a namespace which nominates the member's namespace in a

using-directive; see 3.1363.0.1.

1

The outermost declarative region of a translation unit is also a namespace, called the *global namespace*. A name declared in the global namespace has *global namespace scope* (also called *global scope*). The potential scope of such a name begins at its point of declaration (3.536.1) and ends at the end of the translation unit that is its declarative region. A name with global namespace scope is said to be a *global name*.

3.760.1 Class scope [basic.scope.class]

1

The following rules describe the scope of names declared in classes.

1) The potential scope of a name declared in a class consists not only of the declarative region following the name's point of declaration, but also of all function bodies, default arguments, *exception-specification*s, and *brace-or-equal-initializers* of non-static data members in that class (including such things in nested classes).

2) A name `N` used in a class `S` shall refer to the same declaration in its context and when re-evaluated in the completed scope of `S`. No diagnostic is required for a violation of this rule.

3) If reordering member declarations in a class yields an alternate valid program under (1) and (2), the program is ill-formed, no diagnostic is required.

4) A name declared within a member function hides a declaration of the same name whose scope extends to or past the end of the member function's class.

5) The potential scope of a declaration that extends to or past the end of a class definition also extends to the regions defined by its member definitions, even if the members are defined lexically outside the class (this includes static data member definitions, nested class definitions, and member function definitions, including the member function body and any portion of the declarator part of such definitions which follows the *declarator-id*, including a *parameter-declaration-clause* and any default arguments (8.545.1)).[*Example:*

```
typedef int  c;
enum { i = 1 };

class X {
  char  v[i];                       // error: i refers to ::i
                                    // but when reevaluated is X::i
  int  f() { return sizeof(c); }    // OK: X::c
  char  c;
  enum { i = 2 };
};

typedef char*  T;
struct Y {
  T  a;                             // error: T refers to ::T
                                    // but when reevaluated is Y::T
  typedef long  T;
  T  b;
};

typedef int I;
class D {
  typedef I I;                      // error, even though no reordering involved
```

```
};
```

— *end example*]

1

The name of a class member shall only be used as follows:

— in the scope of its class (as described above) or a class derived (Clause 10) from its class,

— after the `.` operator applied to an expression of the type of its class (5.1194.1) or a class derived from its class,

— after the `->` operator applied to a pointer to an object of its class (5.1194.1) or a class derived from its class,

— after the `::` scope resolution operator (5.398) applied to the name of its class or a class derived from its class.

3.865.1 Enumeration scope [basic.scope.enum]

1 The name of a scoped enumerator (7.1001) has *enumeration scope*. Its potential scope begins at its point of declaration and terminates at the end of the *enum-specifier*.

3.865.2 Template parameter scope [basic.scope.temp]

1

The declarative region of the name of a template parameter of a template *template-parameter* is the smallest *template-parameter-list* in which the name was introduced.

1

The declarative region of the name of a template parameter of a template is the smallest *template-declaration* in which the name was introduced. Only template parameter names belong to this declarative region; any other kind of name introduced by the *declaration* of a *template-declaration* is instead introduced into the same declarative region where it would be introduced as a result of a non-template declaration of the same name. [*Example:*

```
namespace N {
  template<class T> struct A { };              // #1
  template<class U> void f(U) { }              // #2
  struct B {
    template<class V> friend int g(struct C*);  // #3
  };
}
```

The declarative regions of `T`, `U` and `V` are the *template-declaration*s on lines `#1`, `#2` and `#3`, respectively. But the names `A`, `f`, `g` and `C` all belong to the same declarative region — namely, the *namespace-body* of `N`. (`g` is still considered to belong to this declarative region in spite of its being hidden during qualified and unqualified name lookup.) — *end example*]

1

The potential scope of a template parameter name begins at its point of declaration (3.536.1) and ends at the end of its declarative region. [*Note:* This implies that a *template-parameter* can be used in the declaration of subsequent *template-parameter*s and their default arguments but cannot be used in preceding *template-parameter*s or their default arguments. For example,

```
template<class T, T* p, class U = T> class X { /* ... */ };
template<class T> void f(T* p = new T);
```

This also implies that a *template-parameter* can be used in the specification of base classes. For example,

```
template<class T> class X : public Array<T> { /* ... */ };
template<class T> class Y : public T { /* ... */ };
```

The use of a template parameter as a base class implies that a class used as a template argument must be defined and not just declared when the class template is instantiated. — *end note*]

1

The declarative region of the name of a template parameter is nested within the immediately-enclosing declarative region. [*Note:* As a result, a *template-parameter* hides any entity with the same name in an enclosing scope (3.875.1). [*Example:*

```
typedef int N;
template<N X, typename N, template<N Y> class T> struct A;
```

Here, `X` is a non-type template parameter of type `int` and `Y` is a non-type template parameter of the same type as the second template parameter of `A`. — *end example*] — *end note*]

1

[*Note:* Because the name of a template parameter cannot be redeclared within its potential scope (14.1177.1), a template parameter's scope is often its potential scope. However, it is still possible for a template parameter name to be hidden; see 14.1177.1. — *end note*]

3.875.1 Name hiding [basic.scope.hiding]

1

A name can be hidden by an explicit declaration of that same name in a nested declarative region or derived class (10.52).

1

A class name (9.172) or enumeration name (7.1001) can be hidden by the name of a variable, data member, function, or enumerator declared in the same scope. If a class or enumeration name and a variable, data member, function, or enumerator are declared in the same scope (in any order) with the same name, the class or enumeration name is hidden wherever the variable, data member, function, or enumerator name is visible.

1

In a member function definition, the declaration of a name at block scope hides the declaration of a member of the class with the same name; see 3.760.1. The declaration of a member in a derived class (Clause 10) hides the declaration of a member of a base class of the same name; see 10.52.

1

During the lookup of a name qualified by a namespace name, declarations that would otherwise be made visible by a *using-directive* can be hidden by declarations with the same name in the namespace containing the *using-directive;* see (3.1363.0.1).

1 If a name is in scope and is not hidden it is said to be *visible*.

3.923 Name lookup [basic.lookup]

1

The name lookup rules apply uniformly to all names (including *typedef-name*s (7.235.1), *namespace-name*s (7.1142), and *class-name*s (9.172)) wherever the grammar allows such names in the context discussed by a particular rule. Name lookup associates the use of a name with a declaration (3.43) of that name. Name lookup shall find an unambiguous declaration for the name (see 10.52). Name lookup may associate more than one

declaration with a name if it finds the name to be a function name; the declarations are said to form a set of overloaded functions (13.12). Overload resolution (13.88) takes place after name lookup has succeeded. The access rules (Clause 11) are considered only once name lookup and function overload resolution (if applicable) have succeeded. Only after name lookup, function overload resolution (if applicable) and access checking have succeeded are the attributes introduced by the name's declaration used further in expression processing (Clause 5).

1

A name "looked up in the context of an expression" is looked up as an unqualified name in the scope where the expression is found.

1

The injected-class-name of a class (Clause 9) is also considered to be a member of that class for the purposes of name hiding and lookup.

1 [*Note:* 3.1459 discusses linkage issues. The notions of scope, point of declaration and name hiding are discussed in 3.464. — *end note*]

3.952.1 Unqualified name lookup [basic.lookup.unqual]

1

In all the cases listed in 3.952.1, the scopes are searched for a declaration in the order listed in each of the respective categories; name lookup ends as soon as a declaration is found for the name. If no declaration is found, the program is ill-formed.

1

The declarations from the namespace nominated by a *using-directive* become visible in a namespace enclosing the *using-directive*; see 7.1416.1. For the purpose of the unqualified name lookup rules described in 3.952.1, the declarations from the namespace nominated by the *using-directive* are considered members of that enclosing namespace.

1

The lookup for an unqualified name used as the *postfix-expression* of a function call is described in 3.1092.1. [*Note:* For purposes of determining (during parsing) whether an expression is a *postfix-expression* for a function call, the usual name lookup rules apply. The rules in 3.1092.1 have no effect on the syntactic interpretation of an expression. For example,

```
typedef int f;
namespace N {
  struct A {
    friend void f(A &);
    operator int();
    void g(A a) {
      int i = f(a);          // f is the typedef, not the friend
                             // function: equivalent to int(a)
    }
  };
}
```

Because the expression is not a function call, the argument-dependent name lookup (3.1092.1) does not apply and the friend function `f` is not found. — *end note*]

1

A name used in global scope, outside of any function, class or user-declared namespace, shall be declared before its use in global scope.

1

A name used in a user-declared namespace outside of the definition of any function or class shall be declared before its use in that namespace or before its use in a namespace enclosing its namespace.

1

A name used in the definition of a function following the function's *declarator-id*[28] that is a member of namespace `N` (where, only for the purpose of exposition, `N` could represent the global scope) shall be declared before its use in the block in which it is used or in one of its enclosing blocks (6.15) or, shall be declared before its use in namespace `N` or, if `N` is a nested namespace, shall be declared before its use in one of `N`'s enclosing namespaces. [*Example:*

```
namespace A {
  namespace N {
    void f();
  }
}
void A::N::f() {
  i = 5;
  // The following scopes are searched for a declaration of i:
  // 1) outermost block scope of A::N::f, before the use of i
  // 2) scope of namespace N
  // 3) scope of namespace A
  // 4) global scope, before the definition of A::N::f
}
```

— *end example*]

1

A name used in the definition of a class `X` outside of a member function body, default argument, *exception-specification*, *brace-or-equal-initializer* of a non-static data member, or nested class definition[29] shall be declared in one of the following ways:

— before its use in class `X` or be a member of a base class of `X` (10.52), or

— if `X` is a nested class of class `Y` (9.960), before the definition of `X` in `Y`, or shall be a member of a base class of `Y` (this lookup applies in turn to `Y` 's enclosing classes, starting with the innermost enclosing class),[30] or

— if `X` is a local class (9.975) or is a nested class of a local class, before the definition of class `X` in a block enclosing the definition of class `X`, or

— if `X` is a member of namespace `N`, or is a nested class of a class that is a member of `N`, or is a local class or a nested class within a local class of a function that is a member of `N`, before the definition of class `X` in namespace `N` or in one of `N` 's enclosing namespaces.

[*Example:*

```
namespace M {
  class B { };
}
```

28) This refers to unqualified names that occur, for instance, in a type or default argument in the *parameter-declaration-clause* or used in the function body.

29) This refers to unqualified names following the class name; such a name may be used in the *base-clause* or may be used in the class definition.

30) This lookup applies whether the definition of `X` is nested within `Y`'s definition or whether `X`'s definition appears in a namespace scope enclosing `Y` 's definition (9.960).

```
namespace N {
  class Y : public M::B {
    class X {
      int a[i];
    };
  };
}

// The following scopes are searched for a declaration of i:
// 1) scope of class N::Y::X, before the use of i
// 2) scope of class N::Y, before the definition of N::Y::X
// 3) scope of N::Y's base class M::B
// 4) scope of namespace N, before the definition of N::Y
// 5) global scope, before the definition of N
```

— *end example*] [*Note:* When looking for a prior declaration of a class or function introduced by a `friend` declaration, scopes outside of the innermost enclosing namespace scope are not considered; see 7.1215.0.1. — *end note*] [*Note:* 3.760.1 further describes the restrictions on the use of names in a class definition. 9.960 further describes the restrictions on the use of names in nested class definitions. 9.975 further describes the restrictions on the use of names in local class definitions. — *end note*]

1

For the members of a class `X`, a name used in a member function body, in a default argument, in an *exception-specification*, in the *brace-or-equal-initializer* of a non-static data member (9.194), or in the definition of a class member outside of the definition of `X`, following the member's *declarator-id*[31], shall be declared in one of the following ways:

— before its use in the block in which it is used or in an enclosing block (6.15), or

— shall be a member of class `X` or be a member of a base class of `X` (10.52), or

— if `X` is a nested class of class `Y` (9.960), shall be a member of `Y`, or shall be a member of a base class of `Y` (this lookup applies in turn to `Y`'s enclosing classes, starting with the innermost enclosing class),[32] or

— if `X` is a local class (9.975) or is a nested class of a local class, before the definition of class `X` in a block enclosing the definition of class `X`, or

— if `X` is a member of namespace `N`, or is a nested class of a class that is a member of `N`, or is a local class or a nested class within a local class of a function that is a member of `N`, before the use of the name, in namespace `N` or in one of `N` 's enclosing namespaces.

[*Example:*

```
class B { };
namespace M {
  namespace N {
    class X : public B {
      void f();
    };
  }
}
```

31) That is, an unqualified name that occurs, for instance, in a type in the *parameter-declaration-clause* or in the *exception-specification*.

32) This lookup applies whether the member function is defined within the definition of class `X` or whether the member function is defined in a namespace scope enclosing `X`'s definition.

```
void M::N::X::f() {
  i = 16;
}

// The following scopes are searched for a declaration of i:
// 1) outermost block scope of M::N::X::f, before the use of i
// 2) scope of class M::N::X
// 3) scope of M::N::X's base class B
// 4) scope of namespace M::N
// 5) scope of namespace M
// 6) global scope, before the definition of M::N::X::f
```

— *end example*] [*Note:* 9.401 and 9.559 further describe the restrictions on the use of names in member function definitions. 9.960 further describes the restrictions on the use of names in the scope of nested classes. 9.975 further describes the restrictions on the use of names in local class definitions. — *end note*]

1

Name lookup for a name used in the definition of a `friend` function (11.94) defined inline in the class granting friendship shall proceed as described for lookup in member function definitions. If the `friend` function is not defined in the class granting friendship, name lookup in the `friend` function definition shall proceed as described for lookup in namespace member function definitions.

1

In a `friend` declaration naming a member function, a name used in the function declarator and not part of a *template-argument* in the *declarator-id* is first looked up in the scope of the member function's class (10.52). If it is not found, or if the name is part of a *template-argument* in the *declarator-id*, the look up is as described for unqualified names in the definition of the class granting friendship. [*Example:*

```
struct A {
  typedef int AT;
  void f1(AT);
  void f2(float);
  template <class T> void f3();
};
struct B {
  typedef char AT;
  typedef float BT;
  friend void A::f1(AT);       // parameter type is A::AT
  friend void A::f2(BT);       // parameter type is B::BT
  friend void A::f3<AT>();     // template argument is B::AT
};
```

— *end example*]

1 During the lookup for a name used as a default argument (8.545.1) in a function *parameter-declaration-clause* or used in the *expression* of a *mem-initializer* for a constructor (12.1026.1), the function parameter names are visible and hide the names of entities declared in the block, class or namespace scopes containing the function declaration. [*Note:* 8.545.1 further describes the restrictions on the use of names in default arguments. 12.1026.1 further describes the restrictions on the use of names in a *ctor-initializer*. — *end note*]

2

During the lookup of a name used in the *constant-expression* of an *enumerator-definition*, previously declared *enumerator*s of the enumeration are visible and hide the names of entities declared in the block, class, or namespace scopes containing the *enum-specifier*.

1

A name used in the definition of a `static` data member of class `X` (9.595.1) (after the *qualified-id* of the static member) is looked up as if the name was used in a member function of `X`. [*Note:* 9.595.1 further describes the restrictions on the use of names in the definition of a `static` data member. — *end note*]

1

If a variable member of a namespace is defined outside of the scope of its namespace then any name that appears in the definition of the member (after the *declarator-id*) is looked up as if the definition of the member occurred in its namespace. [*Example:*

```
namespace N {
  int i = 4;
  extern int j;
}

int i = 2;

int N::j = i;                    // N::j == 4
```

— *end example*]

1 A name used in the handler for a *function-try-block* (Clause 15) is looked up as if the name was used in the outermost block of the function definition. In particular, the function parameter names shall not be redeclared in the *exception-declaration* nor in the outermost block of a handler for the *function-try-block*. Names declared in the outermost block of the function definition are not found when looked up in the scope of a handler for the *function-try-block*. [*Note:* But function parameter names are found. — *end note*]

2 [*Note:* The rules for name lookup in template definitions are described in 14.1061. — *end note*]

3.1092.1 Argument-dependent name lookup [basic.lookup.argdep]

1

When the *postfix-expression* in a function call (5.955.1) is an *unqualified-id*, other namespaces not considered during the usual unqualified lookup (3.952.1) may be searched, and in those namespaces, namespace-scope friend function or function template declarations (11.94) not otherwise visible may be found. These modifications to the search depend on the types of the arguments (and for template template arguments, the namespace of the template argument). [*Example:*

```
namespace N {
  struct S { };
  void f(S);
}

void g() {
  N::S s;
  f(s);                          // OK: calls N::f
  (f)(s);                        // error: N::f not considered; parentheses
                                 // prevent argument-dependent lookup
}
```

— *end example*]

1

For each argument type `T` in the function call, there is a set of zero or more associated namespaces and a set of zero or more associated classes to be considered. The sets of namespaces and classes is determined entirely by the types of the function arguments (and the namespace of any template template argument).

Typedef names and *using-declaration*s used to specify the types do not contribute to this set. The sets of namespaces and classes are determined in the following way:

— If `T` is a fundamental type, its associated sets of namespaces and classes are both empty.

— If `T` is a class type (including unions), its associated classes are: the class itself; the class of which it is a member, if any; and its direct and indirect base classes. Its associated namespaces are the innermost enclosing namespaces of its associated classes. Furthermore, if `T` is a class template specialization, its associated namespaces and classes also include: the namespaces and classes associated with the types of the template arguments provided for template type parameters (excluding template template parameters); the namespaces of which any template template arguments are members; and the classes of which any member templates used as template template arguments are members. [*Note:* Non-type template arguments do not contribute to the set of associated namespaces. — *end note*]

— If `T` is an enumeration type, its associated namespace is the innermost enclosing namespace of its declaration. If it is a class member, its associated class is the member's class; else it has no associated class.

— If `T` is a pointer to `U` or an array of `U`, its associated namespaces and classes are those associated with `U`.

— If `T` is a function type, its associated namespaces and classes are those associated with the function parameter types and those associated with the return type.

— If `T` is a pointer to a member function of a class `X`, its associated namespaces and classes are those associated with the function parameter types and return type, together with those associated with `X`.

— If `T` is a pointer to a data member of class `X`, its associated namespaces and classes are those associated with the member type together with those associated with `X`.

If an associated namespace is an inline namespace (7.1149.1), its enclosing namespace is also included in the set. If an associated namespace directly contains inline namespaces, those inline namespaces are also included in the set. In addition, if the argument is the name or address of a set of overloaded functions and/or function templates, its associated classes and namespaces are the union of those associated with each of the members of the set, i.e., the classes and namespaces associated with its parameter types and return type. Additionally, if the aforementioned set of overloaded functions is named with a *template-id*, its associated classes and namespaces also include those of its type *template-argument*s and its template *template-argument*s.

1

Let X be the lookup set produced by unqualified lookup (3.952.1) and let Y be the lookup set produced by argument dependent lookup (defined as follows). If X contains

— a declaration of a class member, or

— a block-scope function declaration that is not a *using-declaration*, or

— a declaration that is neither a function or a function template

then Y is empty. Otherwise Y is the set of declarations found in the namespaces associated with the argument types as described below. The set of declarations found by the lookup of the name is the union of X and Y. [*Note:* The namespaces and classes associated with the argument types can include namespaces and classes already considered by the ordinary unqualified lookup. — *end note*] [*Example:*

```
namespace NS {
  class T { };
  void f(T);
  void g(T, int);
}
NS::T parm;
void g(NS::T, float);
int main() {
  f(parm);                      // OK: calls NS::f
  extern void g(NS::T, float);
  g(parm, 1);                   // OK: calls g(NS::T, float)
}
```

— *end example*]

1

When considering an associated namespace, the lookup is the same as the lookup performed when the associated namespace is used as a qualifier (3.1363.0.1) except that:

— Any *using-directives* in the associated namespace are ignored.

— Any namespace-scope friend functions or friend function templates declared in associated classes are visible within their respective namespaces even if they are not visible during an ordinary lookup (11.94).

— All names except those of (possibly overloaded) functions and function templates are ignored.

3.1236.1 Qualified name lookup [basic.lookup.qual]

1

The name of a class or namespace member or enumerator can be referred to after the `::` scope resolution operator (5.398) applied to a *nested-name-specifier* that denotes its class, namespace, or enumeration. If a `::` scope resolution operator in a *nested-name-specifier* is not preceded by a *decltype-specifier*, lookup of the name preceding that `::` considers only namespaces, types, and templates whose specializations are types. If the name found does not designate a namespace or a class, enumeration, or dependent type, the program is ill-formed. [*Example:*

```
class A {
public:
  static int n;
};
int main() {
  int A;
  A::n = 42;        // OK
  A b;              // ill-formed: A does not name a type
}
```

— *end example*]

1 [*Note:* Multiply qualified names, such as `N1::N2::N3::n`, can be used to refer to members of nested classes (9.960) or members of nested namespaces. — *end note*]

2

In a declaration in which the *declarator-id* is a *qualified-id*, names used before the *qualified-id* being declared are looked up in the defining namespace scope; names following the *qualified-id* are looked up in the scope of the member's class or namespace. [*Example:*

```
class X { };
class C {
  class X { };
  static const int number = 50;
  static X arr[number];
};
X C::arr[number];    // ill-formed:
                     // equivalent to: ::X C::arr[C::number];
                     // not to: C::X C::arr[C::number];
```

— *end example*]

1

A name prefixed by the unary scope operator `::` (5.398) is looked up in global scope, in the translation unit where it is used. The name shall be declared in global namespace scope or shall be a name whose declaration is visible in global scope because of a *using-directive* (3.1363.0.1). The use of `::` allows a global name to be referred to even if its identifier has been hidden (3.875.1).

1

A name prefixed by a *nested-name-specifier* that nominates an enumeration type shall represent an *enumerator* of that enumeration.

1

If a *pseudo-destructor-name* (5.1181.1) contains a *nested-name-specifier*, the *type-name*s are looked up as types in the scope designated by the *nested-name-specifier*. Similarly, in a *qualified-id* of the form:

nested-name-specifier$_{opt}$ *class-name* `::` `~` *class-name*

the second *class-name* is looked up in the same scope as the first. [*Example:*

```
struct C {
  typedef int I;
};
typedef int I1, I2;
extern int* p;
extern int* q;
p->C::I::~I();       // I is looked up in the scope of C
q->I1::~I2();        // I2 is looked up in the scope of
                     // the postfix-expression

struct A {
  ~A();
};
typedef A AB;
int main() {
  AB* p;
  p->AB::~AB();      // explicitly calls the destructor for A
}
```

— *end example*] [*Note:* 3.1423.1 describes how name lookup proceeds after the `.` and `->` operators. — *end note*]

3.1282.0.1 Class members [class.qual]

1

If the *nested-name-specifier* of a *qualified-id* nominates a class, the name specified after the *nested-name-specifier* is looked up in the scope of the class (10.52), except for the cases listed below. The name shall

represent one or more members of that class or of one of its base classes (Clause 10). [*Note:* A class member can be referred to using a *qualified-id* at any point in its potential scope (3.760.1). — *end note*] The exceptions to the name lookup rule above are the following:

— a destructor name is looked up as specified in 3.1236.1;

— a *conversion-type-id* of a *conversion-function-id* is looked up in the same manner as a *conversion-type-id* in a class member access (see 3.1423.1);

— the names in a *template-argument* of a *template-id* are looked up in the context in which the entire *postfix-expression* occurs.

— the lookup for a name specified in a *using-declaration* (7.1311.1) also finds class or enumeration names hidden within the same scope (3.875.1).

1

In a lookup in which function names are not ignored[33] and the *nested-name-specifier* nominates a class `C`:

— if the name specified after the *nested-name-specifier*, when looked up in `C`, is the injected-class-name of `C` (Clause 9), or

— in a *using-declaration* (7.1311.1) that is a *member-declaration*, if the name specified after the *nested-name-specifier* is the same as the *identifier* or the *simple-template-id*'s *template-name* in the last component of the *nested-name-specifier*,

the name is instead considered to name the constructor of class `C`. [*Note:* For example, the constructor is not an acceptable lookup result in an *elaborated-type-specifier* so the constructor would not be used in place of the injected-class-name. — *end note*] Such a constructor name shall be used only in the *declarator-id* of a declaration that names a constructor or in a *using-declaration*. [*Example:*

```
struct A { A(); };
struct B: public A { B(); };

A::A() { }
B::B() { }

B::A ba;            // object of type A
A::A a;             // error, A::A is not a type name
struct A::A a2;     // object of type A
```

— *end example*]

1

A class member name hidden by a name in a nested declarative region or by the name of a derived class member can still be found if qualified by the name of its class followed by the `::` operator.

3.1363.0.1 Namespace members [namespace.qual]

1

If the *nested-name-specifier* of a *qualified-id* nominates a namespace, the name specified after the *nested-name-specifier* is looked up in the scope of the namespace. If a *qualified-id* starts with `::`, the name after the `::` is looked up in the global namespace. In either case, the names in a *template-argument* of a *template-id* are looked up in the context in which the entire *postfix-expression* occurs.

33) Lookups in which function names are ignored include names appearing in a *nested-name-specifier*, an *elaborated-type-specifier*, or a *base-specifier*.

1

For a namespace `X` and name `m`, the namespace-qualified lookup set $S(X, m)$ is defined as follows: Let $S'(X, m)$ be the set of all declarations of `m` in `X` and the inline namespace set of `X` (7.1149.1). If $S'(X, m)$ is not empty, $S(X, m)$ is $S'(X, m)$; otherwise, $S(X, m)$ is the union of $S(N_i, m)$ for all namespaces N_i nominated by *using-directives* in `X` and its inline namespace set.

1

Given `X::m` (where `X` is a user-declared namespace), or given `::m` (where X is the global namespace), if $S(X, m)$ is the empty set, the program is ill-formed. Otherwise, if $S(X, m)$ has exactly one member, or if the context of the reference is a *using-declaration* (7.1311.1), $S(X, m)$ is the required set of declarations of `m`. Otherwise if the use of `m` is not one that allows a unique declaration to be chosen from $S(X, m)$, the program is ill-formed. [*Example:*

```
int x;
namespace Y {
  void f(float);
  void h(int);
}

namespace Z {
  void h(double);
}

namespace A {
  using namespace Y;
  void f(int);
  void g(int);
  int i;
}

namespace B {
  using namespace Z;
  void f(char);
  int i;
}

namespace AB {
  using namespace A;
  using namespace B;
  void g();
}

void h()
{
  AB::g();          // g is declared directly in AB,
                    // therefore S is { AB::g() } and AB::g() is chosen
  AB::f(1);         // f is not declared directly in AB so the rules are
                    // applied recursively to A and B;
                    // namespace Y is not searched and Y::f(float)
                    // is not considered;
                    // S is { A::f(int), B::f(char) } and overload
                    // resolution chooses A::f(int)
  AB::f('c');       // as above but resolution chooses B::f(char)

  AB::x++;          // x is not declared directly in AB, and
```

```
                        // is not declared in A or B , so the rules are
                        // applied recursively to Y and Z,
                        // S is { } so the program is ill-formed
  AB::i++;              // i is not declared directly in AB so the rules are
                        // applied recursively to A and B,
                        // S is { A::i , B::i } so the use is ambiguous
                        // and the program is ill-formed
  AB::h(16.8);          // h is not declared directly in AB and
                        // not declared directly in A or B so the rules are
                        // applied recursively to Y and Z,
                        // S is { Y::h(int), Z::h(double) } and overload
                        // resolution chooses Z::h(double)
}
```

1 The same declaration found more than once is not an ambiguity (because it is still a unique declaration). For example:

```
namespace A {
  int a;
}

namespace B {
  using namespace A;
}

namespace C {
  using namespace A;
}

namespace BC {
  using namespace B;
  using namespace C;
}

void f()
{
  BC::a++;            // OK: S is { A::a, A::a }
}

namespace D {
  using A::a;
}

namespace BD {
  using namespace B;
  using namespace D;
}

void g()
{
  BD::a++;            // OK: S is {  A::a,  A::a }
}
```

2 Because each referenced namespace is searched at most once, the following is well-defined:

```
namespace B {
```

```
  int b;
}

namespace A {
  using namespace B;
  int a;
}

namespace B {
  using namespace A;
}

void f()
{
  A::a++;          // OK: a declared directly in A, S is {A::a}
  B::a++;          // OK: both A and B searched (once), S is {A::a}
  A::b++;          // OK: both A and B searched (once), S is {B::b}
  B::b++;          // OK: b declared directly in B, S is {B::b}
}
```

— *end example*]

3 During the lookup of a qualified namespace member name, if the lookup finds more than one declaration of the member, and if one declaration introduces a class name or enumeration name and the other declarations either introduce the same variable, the same enumerator or a set of functions, the non-type name hides the class or enumeration name if and only if the declarations are from the same namespace; otherwise (the declarations are from different namespaces), the program is ill-formed. [*Example:*

```
namespace A {
  struct x { };
  int x;
  int y;
}

namespace B {
  struct y { };
}

namespace C {
  using namespace A;
  using namespace B;
  int i = C::x;     // OK, A::x (of type int )
  int j = C::y;     // ambiguous, A::y or B::y
}
```

— *end example*]

4

In a declaration for a namespace member in which the *declarator-id* is a *qualified-id*, given that the *qualified-id* for the namespace member has the form

nested-name-specifier unqualified-id

the *unqualified-id* shall name a member of the namespace designated by the *nested-name-specifier* or of an element of the inline namespace set (7.1149.1) of that namespace. [*Example:*

```
namespace A {
```

```
  namespace B {
    void f1(int);
  }
  using namespace B;
}
void A::f1(int){ }  // ill-formed, f1 is not a member of A
```

— *end example*] However, in such namespace member declarations, the *nested-name-specifier* may rely on *using-directives* to implicitly provide the initial part of the *nested-name-specifier*. [*Example:*

```
namespace A {
  namespace B {
    void f1(int);
  }
}

namespace C {
  namespace D {
    void f1(int);
  }
}

using namespace A;
using namespace C::D;
void B::f1(int){ }  // OK, defines A::B::f1(int)
```

— *end example*]

3.1395.1 Elaborated type specifiers [basic.lookup.elab]

1

An *elaborated-type-specifier* (7.808.0.1) may be used to refer to a previously declared *class-name* or *enum-name* even though the name has been hidden by a non-type declaration (3.875.1).

1

If the *elaborated-type-specifier* has no *nested-name-specifier*, and unless the *elaborated-type-specifier* appears in a declaration with the following form:

class-key attribute-specifier-seq$_{opt}$ *identifier* ;

the *identifier* is looked up according to 3.952.1 but ignoring any non-type names that have been declared. If the *elaborated-type-specifier* is introduced by the `enum` keyword and this lookup does not find a previously declared *type-name*, the *elaborated-type-specifier* is ill-formed. If the *elaborated-type-specifier* is introduced by the *class-key* and this lookup does not find a previously declared *type-name*, or if the *elaborated-type-specifier* appears in a declaration with the form:

class-key attribute-specifier-seq$_{opt}$ *identifier* ;

the *elaborated-type-specifier* is a declaration that introduces the *class-name* as described in 3.536.1.

1 If the *elaborated-type-specifier* has a *nested-name-specifier*, qualified name lookup is performed, as described in 3.1236.1, but ignoring any non-type names that have been declared. If the name lookup does not find a previously declared *type-name*, the *elaborated-type-specifier* is ill-formed. [*Example:*

```
struct Node {
  struct Node* Next;          // OK: Refers to Node at global scope
  struct Data* Data;          // OK: Declares type Data
                              // at global scope and member Data
```

```
};

struct Data {
  struct Node* Node;            // OK: Refers to Node at global scope
  friend struct ::Glob;         // error: Glob is not declared
                                // cannot introduce a qualified type (7.808.0.1)
  friend struct Glob;           // OK: Refers to (as yet) undeclared Glob
                                // at global scope.
  /* ... */
};

struct Base {
  struct Data;                  // OK: Declares nested Data
  struct ::Data*     thatData;  // OK: Refers to ::Data
  struct Base::Data* thisData;  // OK: Refers to nested Data
  friend class ::Data;          // OK: global Data is a friend
  friend class Data;            // OK: nested Data is a friend
  struct Data { /* ...  */ };   // Defines nested Data
};

struct Data;                    // OK: Redeclares Data at global scope
struct ::Data;                  // error: cannot introduce a qualified type (7.808.0.1)
struct Base::Data;              // error: cannot introduce a qualified type (7.808.0.1)
struct Base::Datum;             // error: Datum undefined
struct Base::Data* pBase;       // OK: refers to nested Data
```

— *end example*]

3.1423.1 Class member access [basic.lookup.classref]

1

In a class member access expression (5.1194.1), if the `.` or `->` token is immediately followed by an *identifier* followed by a `<`, the identifier must be looked up to determine whether the `<` is the beginning of a template argument list (14.224) or a less-than operator. The identifier is first looked up in the class of the object expression. If the identifier is not found, it is then looked up in the context of the entire *postfix-expression* and shall name a class template.

1

If the *id-expression* in a class member access (5.1194.1) is an *unqualified-id*, and the type of the object expression is of a class type `C`, the *unqualified-id* is looked up in the scope of class `C`. For a pseudo-destructor call (5.1181.1), the *unqualified-id* is looked up in the context of the complete *postfix-expression*.

1

If the *unqualified-id* is `~`*type-name*, the *type-name* is looked up in the context of the entire *postfix-expression*. If the type `T` of the object expression is of a class type `C`, the *type-name* is also looked up in the scope of class `C`. At least one of the lookups shall find a name that refers to (possibly cv-qualified) `T`. [*Example:*

```
struct A { };

struct B {
  struct A { };
  void f(::A* a);
};

void B::f(::A* a) {
```

```
  a->~A();                    // OK: lookup in *a finds the injected-class-name
}
```

— *end example*]

1

If the *id-expression* in a class member access is a *qualified-id* of the form

```
class-name-or-namespace-name::...
```

the *class-name-or-namespace-name* following the `.` or `->` operator is first looked up in the class of the object expression and the name, if found, is used. Otherwise it is looked up in the context of the entire *postfix-expression*. [*Note:* See 3.1236.1, which describes the lookup of a name before `::`, which will only find a type or namespace name. — *end note*]

1 If the *qualified-id* has the form

```
::class-name-or-namespace-name::...
```

the *class-name-or-namespace-name* is looked up in global scope as a *class-name* or *namespace-name*.

2 If the *nested-name-specifier* contains a *simple-template-id* (14.224), the names in its *template-arguments* are looked up in the context in which the entire *postfix-expression* occurs.

3

If the *id-expression* is a *conversion-function-id*, its *conversion-type-id* is first looked up in the class of the object expression and the name, if found, is used. Otherwise it is looked up in the context of the entire *postfix-expression*. In each of these lookups, only names that denote types or templates whose specializations are types are considered. [*Example:*

```
struct A { };
namespace N {
  struct A {
    void g() { }
    template <class T> operator T();
  };
}

int main() {
  N::A a;
  a.operator A();             // calls N::A::operator N::A
}
```

— *end example*]

3.1457.1 Using-directives and namespace aliases [basic.lookup.udir]

1

In a *using-directive* or *namespace-alias-definition*, during the lookup for a *namespace-name* or for a name in a *nested-name-specifier* only namespace names are considered.

3.1459 Program and linkage [basic.link]

1

A *program* consists of one or more *translation units* (Clause 2) linked together. A translation unit consists of a sequence of declarations.

translation-unit:
  declaration-seq$_{opt}$

1

A name is said to have *linkage* when it might denote the same object, reference, function, type, template, namespace or value as a name introduced by a declaration in another scope:

— When a name has *external linkage* , the entity it denotes can be referred to by names from scopes of other translation units or from other scopes of the same translation unit.

— When a name has *internal linkage* , the entity it denotes can be referred to by names from other scopes in the same translation unit.

— When a name has *no linkage* , the entity it denotes cannot be referred to by names from other scopes.

1

A name having namespace scope (3.736.1) has internal linkage if it is the name of

— a variable, function or function template that is explicitly declared `static`; or,

— a non-volatile variable that is explicitly declared `const` or `constexpr` and neither explicitly declared `extern` nor previously declared to have external linkage; or

— a data member of an anonymous union.

1

An unnamed namespace or a namespace declared directly or indirectly within an unnamed namespace has internal linkage. All other namespaces have external linkage. A name having namespace scope that has not been given internal linkage above has the same linkage as the enclosing namespace if it is the name of

— a variable; or

— a function; or

— a named class (Clause 9), or an unnamed class defined in a typedef declaration in which the class has the typedef name for linkage purposes (7.235.1); or

— a named enumeration (7.1001), or an unnamed enumeration defined in a typedef declaration in which the enumeration has the typedef name for linkage purposes (7.235.1); or

— an enumerator belonging to an enumeration with linkage; or

— a template.

1

In addition, a member function, static data member, a named class or enumeration of class scope, or an unnamed class or enumeration defined in a class-scope typedef declaration such that the class or enumeration has the typedef name for linkage purposes (7.235.1), has external linkage if the name of the class has external linkage.

1

The name of a function declared in block scope and the name of a variable declared by a block scope `extern` declaration have linkage. If there is a visible declaration of an entity with linkage having the same name and type, ignoring entities declared outside the innermost enclosing namespace scope, the block scope declaration declares that same entity and receives the linkage of the previous declaration. If there is more than one such matching entity, the program is ill-formed. Otherwise, if no matching entity is found, the block scope entity receives external linkage.[*Example:*

```
static void f();
static int i = 0;              // #1
void g() {
  extern void f();             // internal linkage
  int i;                       // #2 i has no linkage
  {
    extern void f();           // internal linkage
    extern int i;              // #3 external linkage
  }
}
```

There are three objects named `i` in this program. The object with internal linkage introduced by the declaration in global scope (line `#1`), the object with automatic storage duration and no linkage introduced by the declaration on line `#2`, and the object with static storage duration and external linkage introduced by the declaration on line `#3`. — *end example*]

1

When a block scope declaration of an entity with linkage is not found to refer to some other declaration, then that entity is a member of the innermost enclosing namespace. However such a declaration does not introduce the member name in its namespace scope. [*Example:*

```
namespace X {
  void p() {
    q();                       // error: q not yet declared
    extern void q();           // q is a member of namespace X
  }

  void middle() {
    q();                       // error: q not yet declared
  }

  void q() { /* ...  */ }      // definition of X::q
}

void q() { /* ...  */ }        // some other, unrelated q
```

— *end example*]

1

Names not covered by these rules have no linkage. Moreover, except as noted, a name declared at block scope (3.694.1) has no linkage. A type is said to have linkage if and only if:

— it is a class or enumeration type that is named (or has a name for linkage purposes (7.235.1)) and the name has linkage; or

— it is an unnamed class or enumeration member of a class with linkage; or

— it is a specialization of a class template (Clause 14)[34]; or

— it is a fundamental type (3.3151.1); or

— it is a compound type (3.3568.1) other than a class or enumeration, compounded exclusively from types that have linkage; or

34) A class template always has external linkage, and the requirements of 14.349.1 and 14.364.1 ensure that the template arguments will also have appropriate linkage.

— it is a cv-qualified (3.3640.1) version of a type that has linkage.

A type without linkage shall not be used as the type of a variable or function with external linkage unless

— the entity has C language linkage (7.1477), or

— the entity is declared within an unnamed namespace (7.1149.1), or

— the entity is not odr-used (3.91) or is defined in the same translation unit.

[*Note:* In other words, a type without linkage contains a class or enumeration that cannot be named outside its translation unit. An entity with external linkage declared using such a type could not correspond to any other entity in another translation unit of the program and thus must be defined in the translation unit if it is odr-used. Also note that classes with linkage may contain members whose types do not have linkage, and that typedef names are ignored in the determination of whether a type has linkage. — *end note*]

[*Example:*

```
template <class T> struct B {
  void g(T) { }
  void h(T);
  friend void i(B, T) { }
};

void f() {
  struct A { int x; };  // no linkage
  A a = { 1 };
  B<A> ba;              // declares B<A>::g(A) and B<A>::h(A)
  ba.g(a);              // OK
  ba.h(a);              // error: B<A>::h(A) not defined in the translation unit
  i(ba, a);             // OK
}
```

— *end example*]

1

Two names that are the same (Clause 3) and that are declared in different scopes shall denote the same variable, function, type, enumerator, template or namespace if

— both names have external linkage or else both names have internal linkage and are declared in the same translation unit; and

— both names refer to members of the same namespace or to members, not by inheritance, of the same class; and

— when both names denote functions, the parameter-type-lists of the functions (8.360.1) are identical; and

— when both names denote function templates, the signatures (14.975.0.1) are the same.

1

After all adjustments of types (during which typedefs (7.235.1) are replaced by their definitions), the types specified by all declarations referring to a given variable or function shall be identical, except that declarations for an array object can specify array types that differ by the presence or absence of a major array bound (8.251.1). A violation of this rule on type identity does not require a diagnostic.

1

[*Note:* Linkage to non-C++ declarations can be achieved using a *linkage-specification* (7.1477). — *end note*]

3.1721 Start and termination [basic.start]

3.1721.1 Main function [basic.start.main]

1

A program shall contain a global function called `main`, which is the designated start of the program. It is implementation-defined whether a program in a freestanding environment is required to define a `main` function. [*Note:* In a freestanding environment, start-up and termination is implementation-defined; start-up contains the execution of constructors for objects of namespace scope with static storage duration; termination contains the execution of destructors for objects with static storage duration. — *end note*]

1

An implementation shall not predefine the `main` function. This function shall not be overloaded. It shall have a declared return type of type `int`, but otherwise its type is implementation-defined. An implementation shall allow both

— a function of `()` returning `int` and

— a function of `(int`, pointer to pointer to `char)` returning `int`

as the type of `main` (8.360.1). In the latter form, for purposes of exposition, the first function parameter is called `argc` and the second function parameter is called `argv`, where `argc` shall be the number of arguments passed to the program from the environment in which the program is run. If `argc` is nonzero these arguments shall be supplied in `argv[0]` through `argv[argc-1]` as pointers to the initial characters of null-terminated multibyte strings (NTMBS s) (17.26.0.0.0.1) and `argv[0]` shall be the pointer to the initial character of a NTMBS that represents the name used to invoke the program or `""`. The value of `argc` shall be non-negative. The value of `argv[argc]` shall be 0. [*Note:* It is recommended that any further (optional) parameters be added after `argv`. — *end note*]

1

The function `main` shall not be used within a program. The linkage (3.1459) of `main` is implementation-defined. A program that defines `main` as deleted or that declares `main` to be `inline`, `static`, or `constexpr` is ill-formed. The name `main` is not otherwise reserved. [*Example:* member functions, classes, and enumerations can be called `main`, as can entities in other namespaces. — *end example*]

1

Terminating the program without leaving the current block (e.g., by calling the function `std::exit(int)` (18.127)) does not destroy any objects with automatic storage duration (12.807). If `std::exit` is called to end a program during the destruction of an object with static or thread storage duration, the program has undefined behavior.

1

A return statement in `main` has the effect of leaving the main function (destroying any objects with automatic storage duration) and calling `std::exit` with the return value as the argument. If control reaches the end of `main` without encountering a `return` statement, the effect is that of executing

```
return 0;
```

3.1937.1 Initialization of non-local variables [basic.start.init]

1

There are two broad classes of named non-local variables: those with static storage duration (3.2242.1) and those with thread storage duration (3.2291.1). Non-local variables with static storage duration are initialized as a consequence of program initiation. Non-local variables with thread storage duration are initialized as a consequence of thread execution. Within each of these phases of initiation, initialization occurs as follows.

1

Variables with static storage duration (3.2242.1) or thread storage duration (3.2291.1) shall be zero-initialized (8.821) before any other initialization takes place. A *constant initializer* for an object `o` is an expression that is a constant expression, except that it may also invoke `constexpr` constructors for `o` and its subobjects even if those objects are of non-literal class types [*Note:* such a class may have a non-trivial destructor — *end note*]. *Constant initialization* is performed:

— if each full-expression (including implicit conversions) that appears in the initializer of a reference with static or thread storage duration is a constant expression (5.3643) and the reference is bound to an lvalue designating an object with static storage duration, to a temporary (see 12.306), or to a function;

— if an object with static or thread storage duration is initialized by a constructor call, and if the initialization full-expression is a constant initializer for the object;

— if an object with static or thread storage duration is not initialized by a constructor call and if either the object is value-initialized or every full-expression that appears in its initializer is a constant expression.

Together, zero-initialization and constant initialization are called *static initialization*; all other initialization is *dynamic initialization*. Static initialization shall be performed before any dynamic initialization takes place. Dynamic initialization of a non-local variable with static storage duration is either ordered or unordered. Definitions of explicitly specialized class template static data members have ordered initialization. Other class template static data members (i.e., implicitly or explicitly instantiated specializations) have unordered initialization. Other non-local variables with static storage duration have ordered initialization. Variables with ordered initialization defined within a single translation unit shall be initialized in the order of their definitions in the translation unit. If a program starts a thread (30.25), the subsequent initialization of a variable is unsequenced with respect to the initialization of a variable defined in a different translation unit. Otherwise, the initialization of a variable is indeterminately sequenced with respect to the initialization of a variable defined in a different translation unit. If a program starts a thread, the subsequent unordered initialization of a variable is unsequenced with respect to every other dynamic initialization. Otherwise, the unordered initialization of a variable is indeterminately sequenced with respect to every other dynamic initialization. [*Note:* This definition permits initialization of a sequence of ordered variables concurrently with another sequence. — *end note*] [*Note:* The initialization of local static variables is described in 6.419. — *end note*]

1

An implementation is permitted to perform the initialization of a non-local variable with static storage duration as a static initialization even if such initialization is not required to be done statically, provided that

— the dynamic version of the initialization does not change the value of any other object of namespace scope prior to its initialization, and

— the static version of the initialization produces the same value in the initialized variable as would be produced by the dynamic initialization if all variables not required to be initialized statically were initialized dynamically.

[*Note:* As a consequence, if the initialization of an object `obj1` refers to an object `obj2` of namespace scope potentially requiring dynamic initialization and defined later in the same translation unit, it is unspecified

whether the value of `obj2` used will be the value of the fully initialized `obj2` (because `obj2` was statically initialized) or will be the value of `obj2` merely zero-initialized. For example,

```
inline double fd() { return 1.0; }
extern double d1;
double d2 = d1;      // unspecified:
                     // may be statically initialized to 0.0 or
                     // dynamically initialized to 0.0 if d1 is
                     // dynamically initialized, or 1.0 otherwise
double d1 = fd();    // may be initialized statically or dynamically to 1.0
```

— *end note*]

1

It is implementation-defined whether the dynamic initialization of a non-local variable with static storage duration is done before the first statement of `main`. If the initialization is deferred to some point in time after the first statement of `main`, it shall occur before the first odr-use (3.91) of any function or variable defined in the same translation unit as the variable to be initialized.[35] [*Example:*

```
// - File 1 -
#include "a.h"
#include "b.h"
B b;
A::A(){
  b.Use();
}

// - File 2 -
#include "a.h"
A a;

// - File 3 -
#include "a.h"
#include "b.h"
extern A a;
extern B b;

int main() {
  a.Use();
  b.Use();
}
```

It is implementation-defined whether either `a` or `b` is initialized before `main` is entered or whether the initializations are delayed until `a` is first odr-used in `main`. In particular, if `a` is initialized before `main` is entered, it is not guaranteed that `b` will be initialized before it is odr-used by the initialization of `a`, that is, before `A::A` is called. If, however, `a` is initialized at some point after the first statement of `main`, `b` will be initialized prior to its use in `A::A`. — *end example*]

1

It is implementation-defined whether the dynamic initialization of a non-local variable with static or thread storage duration is done before the first statement of the initial function of the thread. If the initialization is deferred to some point in time after the first statement of the initial function of the thread, it shall occur

35) A non-local variable with static storage duration having initialization with side-effects must be initialized even if it is not odr-used (3.91, 3.2242.1).

before the first odr-use (3.91) of any variable with thread storage duration defined in the same translation unit as the variable to be initialized.

1

If the initialization of a non-local variable with static or thread storage duration exits via an exception, `std::terminate` is called (15.308.1).

3.2200.1 Termination [basic.start.term]

1

Destructors (12.807) for initialized objects (that is, objects whose lifetime (3.2563) has begun) with static storage duration are called as a result of returning from `main` and as a result of calling `std::exit` (18.127). Destructors for initialized objects with thread storage duration within a given thread are called as a result of returning from the initial function of that thread and as a result of that thread calling `std::exit`. The completions of the destructors for all initialized objects with thread storage duration within that thread are sequenced before the initiation of the destructors of any object with static storage duration. If the completion of the constructor or dynamic initialization of an object with thread storage duration is sequenced before that of another, the completion of the destructor of the second is sequenced before the initiation of the destructor of the first. If the completion of the constructor or dynamic initialization of an object with static storage duration is sequenced before that of another, the completion of the destructor of the second is sequenced before the initiation of the destructor of the first. [*Note:* This definition permits concurrent destruction. — *end note*] If an object is initialized statically, the object is destroyed in the same order as if the object was dynamically initialized. For an object of array or class type, all subobjects of that object are destroyed before any block-scope object with static storage duration initialized during the construction of the subobjects is destroyed. If the destruction of an object with static or thread storage duration exits via an exception, `std::terminate` is called (15.308.1).

1

If a function contains a block-scope object of static or thread storage duration that has been destroyed and the function is called during the destruction of an object with static or thread storage duration, the program has undefined behavior if the flow of control passes through the definition of the previously destroyed block-scope object. Likewise, the behavior is undefined if the block-scope object is used indirectly (i.e., through a pointer) after its destruction.

1

If the completion of the initialization of an object with static storage duration is sequenced before a call to `std::atexit` (see `<cstdlib>`, 18.127), the call to the function passed to `std::atexit` is sequenced before the call to the destructor for the object. If a call to `std::atexit` is sequenced before the completion of the initialization of an object with static storage duration, the call to the destructor for the object is sequenced before the call to the function passed to `std::atexit`. If a call to `std::atexit` is sequenced before another call to `std::atexit`, the call to the function passed to the second `std::atexit` call is sequenced before the call to the function passed to the first `std::atexit` call.

1

If there is a use of a standard library object or function not permitted within signal handlers (18.295) that does not happen before (1.859) completion of destruction of objects with static storage duration and execution of `std::atexit` registered functions (18.127), the program has undefined behavior. [*Note:* If there is a use of an object with static storage duration that does not happen before the object's destruction, the program has undefined behavior. Terminating every thread before a call to `std::exit` or the exit from `main` is sufficient, but not necessary, to satisfy these requirements. These requirements permit thread managers as static-storage-duration objects. — *end note*]

1 Calling the function `std::abort()` declared in `<cstdlib>` terminates the program without executing any

destructors and without calling the functions passed to `std::atexit()` or `std::at_quick_exit()`.

3.2235 Storage duration [basic.stc]

1

Storage duration is the property of an object that defines the minimum potential lifetime of the storage containing the object. The storage duration is determined by the construct used to create the object and is one of the following:

— static storage duration

— thread storage duration

— automatic storage duration

— dynamic storage duration

1

Static, thread, and automatic storage durations are associated with objects introduced by declarations (3.43) and implicitly created by the implementation (12.306). The dynamic storage duration is associated with objects created with `operator new` (5.2221.1).

1

The storage duration categories apply to references as well. The lifetime of a reference is its storage duration.

3.2242.1 Static storage duration [basic.stc.static]

1

All variables which do not have dynamic storage duration, do not have thread storage duration, and are not local have *static storage duration*. The storage for these entities shall last for the duration of the program (3.1937.1, 3.2200.1).

1

If a variable with static storage duration has initialization or a destructor with side effects, it shall not be eliminated even if it appears to be unused, except that a class object or its copy/move may be eliminated as specified in 12.1577.

1

The keyword `static` can be used to declare a local variable with static storage duration. [*Note:* 6.419 describes the initialization of local `static` variables; 3.2200.1 describes the destruction of local `static` variables. — *end note*]

1

The keyword `static` applied to a class data member in a class definition gives the data member static storage duration.

3.2291.1 Thread storage duration [basic.stc.thread]

1

All variables declared with the `thread_local` keyword have *thread storage duration*. The storage for these entities shall last for the duration of the thread in which they are created. There is a distinct object or reference per thread, and use of the declared name refers to the entity associated with the current thread.

1

A variable with thread storage duration shall be initialized before its first odr-use (3.91) and, if constructed, shall be destroyed on thread exit.

3.2301.1 Automatic storage duration [basic.stc.auto]

1

Block-scope variables explicitly declared `register` or not explicitly declared `static` or `extern` have *automatic storage duration*. The storage for these entities lasts until the block in which they are created exits.

1 [*Note:* These variables are initialized and destroyed as described in 6.419. — *end note*]

2

If a variable with automatic storage duration has initialization or a destructor with side effects, it shall not be destroyed before the end of its block, nor shall it be eliminated as an optimization even if it appears to be unused, except that a class object or its copy/move may be eliminated as specified in 12.1577.

3.2331.1 Dynamic storage duration [basic.stc.dynamic]

1

Objects can be created dynamically during program execution (1.430), using *new-expression*s (5.2221.1), and destroyed using *delete-expression*s (5.2455.1). A C++ implementation provides access to, and management of, dynamic storage via the global *allocation functions* `operator new` and `operator new[]` and the global *deallocation functions* `operator delete` and `operator delete[]`.

1

The library provides default definitions for the global allocation and deallocation functions. Some global allocation and deallocation functions are replaceable (18.159.1). A C++ program shall provide at most one definition of a replaceable allocation or deallocation function. Any such function definition replaces the default version provided in the library (17.428.0.3). The following allocation and deallocation functions (18.159) are implicitly declared in global scope in each translation unit of a program.

```
void* operator new(std::size_t);
void* operator new[](std::size_t);
void operator delete(void*) noexcept;
void operator delete[](void*) noexcept;
void operator delete(void*, std::size_t) noexcept;
void operator delete[](void*, std::size_t) noexcept;
```

These implicit declarations introduce only the function names `operator new`, `operator new[]`, `operator delete`, and `operator delete[]`. [*Note:* The implicit declarations do not introduce the names `std`, `std::size_t`, or any other names that the library uses to declare these names. Thus, a *new-expression*, *delete-expression* or function call that refers to one of these functions without including the header `<new>` is well-formed. However, referring to `std` or `std::size_t` is ill-formed unless the name has been declared by including the appropriate header. — *end note*] Allocation and/or deallocation functions can also be declared and defined for any class (12.988).

1

Any allocation and/or deallocation functions defined in a C++ program, including the default versions in the library, shall conform to the semantics specified in 3.2361.0.1 and 3.2428.0.1.

3.2361.0.1 Allocation functions [basic.stc.dynamic.allocation]

1

An allocation function shall be a class member function or a global function; a program is ill-formed if an allocation function is declared in a namespace scope other than global scope or declared static in global scope. The return type shall be `void*`. The first parameter shall have type `std::size_t` (18.2). The first parameter shall not have an associated default argument (8.545.1). The value of the first parameter shall be

interpreted as the requested size of the allocation. An allocation function can be a function template. Such a template shall declare its return type and first parameter as specified above (that is, template parameter types shall not be used in the return type and first parameter type). Template allocation functions shall have two or more parameters.

1

The allocation function attempts to allocate the requested amount of storage. If it is successful, it shall return the address of the start of a block of storage whose length in bytes shall be at least as large as the requested size. There are no constraints on the contents of the allocated storage on return from the allocation function. The order, contiguity, and initial value of storage allocated by successive calls to an allocation function are unspecified. The pointer returned shall be suitably aligned so that it can be converted to a pointer of any complete object type with a fundamental alignment requirement (3.3924) and then used to access the object or array in the storage allocated (until the storage is explicitly deallocated by a call to a corresponding deallocation function). Even if the size of the space requested is zero, the request can fail. If the request succeeds, the value returned shall be a non-null pointer value (4.579) `p0` different from any previously returned value `p1`, unless that value `p1` was subsequently passed to an `operator delete`. The effect of indirecting through a pointer returned as a request for zero size is undefined.[36]

1

An allocation function that fails to allocate storage can invoke the currently installed new-handler function (18.226.0.1), if any. [*Note:* A program-supplied allocation function can obtain the address of the currently installed `new_handler` using the `std::get_new_handler` function (18.226.0.2). — *end note*] If an allocation function declared with a non-throwing *exception-specification* (15.228) fails to allocate storage, it shall return a null pointer. Any other allocation function that fails to allocate storage shall indicate failure only by throwing an exception (15.7) of a type that would match a handler (15.146) of type `std::bad_alloc` (18.223.1.1).

1

A global allocation function is only called as the result of a new expression (5.2221.1), or called directly using the function call syntax (5.955.1), or called indirectly through calls to the functions in the C++ standard library. [*Note:* In particular, a global allocation function is not called to allocate storage for objects with static storage duration (3.2242.1), for objects or references with thread storage duration (3.2291.1), for objects of type `std::type_info` (5.1393.1), or for an exception object (15.7). — *end note*]

3.2428.0.1 Deallocation functions [basic.stc.dynamic.deallocation]

1

Deallocation functions shall be class member functions or global functions; a program is ill-formed if deallocation functions are declared in a namespace scope other than global scope or declared static in global scope.

1

Each deallocation function shall return `void` and its first parameter shall be `void*`. A deallocation function can have more than one parameter. The global `operator delete` with exactly one parameter is a usual (non-placement) deallocation function. The global `operator delete` with exactly two parameters, the second of which has type `std::size_t`, is a usual deallocation function. Similarly, the global `operator delete[]` with exactly one parameter is a usual deallocation function. The global `operator delete[]` with exactly two parameters, the second of which has type `std::size_t`, is a usual deallocation function.[37] If a class `T`

36) The intent is to have `operator new()` implementable by calling `std::malloc()` or `std::calloc()`, so the rules are substantially the same. C++ differs from C in requiring a zero request to return a non-null pointer.

37) This deallocation function precludes use of an allocation function `void operator new(std::size_t, std::size_t)` as a placement allocation function (C.3.2).

has a member deallocation function named `operator delete` with exactly one parameter, then that function is a usual deallocation function. If class `T` does not declare such an `operator delete` but does declare a member deallocation function named `operator delete` with exactly two parameters, the second of which has type `std::size_t`, then this function is a usual deallocation function. Similarly, if a class `T` has a member deallocation function named `operator delete[]` with exactly one parameter, then that function is a usual (non-placement) deallocation function. If class `T` does not declare such an `operator delete[]` but does declare a member deallocation function named `operator delete[]` with exactly two parameters, the second of which has type `std::size_t`, then this function is a usual deallocation function. A deallocation function can be an instance of a function template. Neither the first parameter nor the return type shall depend on a template parameter. [*Note:* That is, a deallocation function template shall have a first parameter of type `void*` and a return type of `void` (as specified above). — *end note*] A deallocation function template shall have two or more function parameters. A template instance is never a usual deallocation function, regardless of its signature.

1

If a deallocation function terminates by throwing an exception, the behavior is undefined. The value of the first argument supplied to a deallocation function may be a null pointer value; if so, and if the deallocation function is one supplied in the standard library, the call has no effect. Otherwise, the behavior is undefined if the value supplied to `operator delete(void*)` in the standard library is not one of the values returned by a previous invocation of either `operator new(std::size_t)` or `operator new(std::size_t, const std::nothrow_t&)` in the standard library, and the behavior is undefined if the value supplied to `operator delete[](void*)` in the standard library is not one of the values returned by a previous invocation of either `operator new[](std::size_t)` or `operator new[](std::size_t, const std::nothrow_t&)` in the standard library.

1

If the argument given to a deallocation function in the standard library is a pointer that is not the null pointer value (4.579), the deallocation function shall deallocate the storage referenced by the pointer, rendering invalid all pointers referring to any part of the deallocated storage. Indirection through an invalid pointer value and passing an invalid pointer value to a deallocation function have undefined behavior. Any other use of an invalid pointer value has implementation-defined behavior.[38]

3.2532.0.1 Safely-derived pointers [basic.stc.dynamic.safety]

1

A *traceable pointer object* is

— an object of an object pointer type (3.3568.1), or

— an object of an integral type that is at least as large as `std::intptr_t`, or

— a sequence of elements in an array of narrow character type (3.3151.1), where the size and alignment of the sequence match those of some object pointer type.

1

A pointer value is a *safely-derived pointer* to a dynamic object only if it has an object pointer type and it is one of the following:

— the value returned by a call to the C++ standard library implementation of `::operator new(std::size_t)`;[39]

38) Some implementations might define that copying an invalid pointer value causes a system-generated runtime fault.

39) This section does not impose restrictions on indirection through pointers to memory not allocated by `::operator new`. This maintains the ability of many C++ implementations to use binary libraries and components written in other languages. In particular, this applies to C binaries, because indirection through pointers to memory allocated by `std::malloc` is not restricted.

— the result of taking the address of an object (or one of its subobjects) designated by an lvalue resulting from indirection through a safely-derived pointer value;

— the result of well-defined pointer arithmetic (5.2882) using a safely-derived pointer value;

— the result of a well-defined pointer conversion (4.579, 5.2765) of a safely-derived pointer value;

— the result of a `reinterpret_cast` of a safely-derived pointer value;

— the result of a `reinterpret_cast` of an integer representation of a safely-derived pointer value;

— the value of an object whose value was copied from a traceable pointer object, where at the time of the copy the source object contained a copy of a safely-derived pointer value.

1

An integer value is an *integer representation of a safely-derived pointer* only if its type is at least as large as `std::intptr_t` and it is one of the following:

— the result of a `reinterpret_cast` of a safely-derived pointer value;

— the result of a valid conversion of an integer representation of a safely-derived pointer value;

— the value of an object whose value was copied from a traceable pointer object, where at the time of the copy the source object contained an integer representation of a safely-derived pointer value;

— the result of an additive or bitwise operation, one of whose operands is an integer representation of a safely-derived pointer value `P`, if that result converted by `reinterpret_cast<void*>` would compare equal to a safely-derived pointer computable from `reinterpret_cast<void*>(P)`.

1

An implementation may have *relaxed pointer safety*, in which case the validity of a pointer value does not depend on whether it is a safely-derived pointer value. Alternatively, an implementation may have *strict pointer safety*, in which case a pointer value referring to an object with dynamic storage duration that is not a safely-derived pointer value is an invalid pointer value unless the referenced complete object has previously been declared reachable (20.85.1). [*Note:* the effect of using an invalid pointer value (including passing it to a deallocation function) is undefined, see 3.2428.0.1. This is true even if the unsafely-derived pointer value might compare equal to some safely-derived pointer value. — *end note*] It is implementation defined whether an implementation has relaxed or strict pointer safety.

3.2554.1 Duration of subobjects [basic.stc.inherit]

1

The storage duration of member subobjects, base class subobjects and array elements is that of their complete object (1.319).

3.2563 Object lifetime [basic.life]

1

The *lifetime* of an object is a runtime property of the object. An object is said to have non-trivial initialization if it is of a class or aggregate type and it or one of its members is initialized by a constructor other than a trivial default constructor. [*Note:* initialization by a trivial copy/move constructor is non-trivial initialization. — *end note*] The lifetime of an object of type `T` begins when:

— storage with the proper alignment and size for type `T` is obtained, and

— if the object has non-trivial initialization, its initialization is complete.

The lifetime of an object of type `T` ends when:

— if `T` is a class type with a non-trivial destructor (12.807), the destructor call starts, or

— the storage which the object occupies is reused or released.

1

[*Note:* The lifetime of an array object starts as soon as storage with proper size and alignment is obtained, and its lifetime ends when the storage which the array occupies is reused or released. 12.1026.1 describes the lifetime of base and member subobjects. — *end note*]

1

The properties ascribed to objects throughout this International Standard apply for a given object only during its lifetime. [*Note:* In particular, before the lifetime of an object starts and after its lifetime ends there are significant restrictions on the use of the object, as described below, in 12.1026.1 and in 12.1483. Also, the behavior of an object under construction and destruction might not be the same as the behavior of an object whose lifetime has started and not ended. 12.1026.1 and 12.1483 describe the behavior of objects during the construction and destruction phases. — *end note*]

1

A program may end the lifetime of any object by reusing the storage which the object occupies or by explicitly calling the destructor for an object of a class type with a non-trivial destructor. For an object of a class type with a non-trivial destructor, the program is not required to call the destructor explicitly before the storage which the object occupies is reused or released; however, if there is no explicit call to the destructor or if a *delete-expression* (5.2455.1) is not used to release the storage, the destructor shall not be implicitly called and any program that depends on the side effects produced by the destructor has undefined behavior.

1

Before the lifetime of an object has started but after the storage which the object will occupy has been allocated[40] or, after the lifetime of an object has ended and before the storage which the object occupied is reused or released, any pointer that refers to the storage location where the object will be or was located may be used but only in limited ways. For an object under construction or destruction, see 12.1483. Otherwise, such a pointer refers to allocated storage (3.2428.0.1), and using the pointer as if the pointer were of type `void*`, is well-defined. Indirection through such a pointer is permitted but the resulting lvalue may only be used in limited ways, as described below. The program has undefined behavior if:

— the object will be or was of a class type with a non-trivial destructor and the pointer is used as the operand of a *delete-expression*,

— the pointer is used to access a non-static data member or call a non-static member function of the object, or

— the pointer is implicitly converted (4.579) to a pointer to a virtual base class, or

— the pointer is used as the operand of a `static_cast` (5.1443.1), except when the conversion is to pointer to *cv* `void`, or to pointer to *cv* `void` and subsequently to pointer to either *cv* `char` or *cv* `unsigned char`, or

— the pointer is used as the operand of a `dynamic_cast` (5.1295.1). [*Example:*

```
#include <cstdlib>

struct B {
  virtual void f();
```

40) For example, before the construction of a global object of non-POD class type (12.1483).

```
  void mutate();
  virtual ~B();
};

struct D1 : B { void f(); };
struct D2 : B { void f(); };

void B::mutate() {
  new (this) D2;     // reuses storage — ends the lifetime of *this
  f();               // undefined behavior
  ... = this;        // OK, this points to valid memory
}

void g() {
  void* p = std::malloc(sizeof(D1) + sizeof(D2));
  B* pb = new (p) D1;
  pb->mutate();
  &pb;               // OK: pb points to valid memory
  void* q = pb;      // OK: pb points to valid memory
  pb->f();           // undefined behavior, lifetime of *pb has ended
}
```

— *end example*]

1

Similarly, before the lifetime of an object has started but after the storage which the object will occupy has been allocated or, after the lifetime of an object has ended and before the storage which the object occupied is reused or released, any glvalue that refers to the original object may be used but only in limited ways. For an object under construction or destruction, see 12.1483. Otherwise, such a glvalue refers to allocated storage (3.2428.0.1), and using the properties of the glvalue that do not depend on its value is well-defined. The program has undefined behavior if:

— an lvalue-to-rvalue conversion (4.127) is applied to such a glvalue,

— the glvalue is used to access a non-static data member or call a non-static member function of the object, or

— the glvalue is bound to a reference to a virtual base class (8.2156.1), or

— the glvalue is used as the operand of a `dynamic_cast` (5.1295.1) or as the operand of `typeid`.

1

If, after the lifetime of an object has ended and before the storage which the object occupied is reused or released, a new object is created at the storage location which the original object occupied, a pointer that pointed to the original object, a reference that referred to the original object, or the name of the original object will automatically refer to the new object and, once the lifetime of the new object has started, can be used to manipulate the new object, if:

— the storage for the new object exactly overlays the storage location which the original object occupied, and

— the new object is of the same type as the original object (ignoring the top-level cv-qualifiers), and

— the type of the original object is not const-qualified, and, if a class type, does not contain any non-static data member whose type is const-qualified or a reference type, and

— the original object was a most derived object (1.319) of type `T` and the new object is a most derived object of type `T` (that is, they are not base class subobjects). [*Example:*

```
struct C {
  int i;
  void f();
  const C& operator=( const C& );
};

const C& C::operator=( const C& other) {
  if ( this != &other ) {
    this->~C();                 // lifetime of *this ends
    new (this) C(other);        // new object of type C created
    f();                        // well-defined
  }
  return *this;
}

C c1;
C c2;
c1 = c2;                        // well-defined
c1.f();                         // well-defined; c1 refers to a new object of type C
```

— *end example*]

1

If a program ends the lifetime of an object of type `T` with static (3.2242.1), thread (3.2291.1), or automatic (3.2301.1) storage duration and if `T` has a non-trivial destructor,[41] the program must ensure that an object of the original type occupies that same storage location when the implicit destructor call takes place; otherwise the behavior of the program is undefined. This is true even if the block is exited with an exception. [*Example:*

```
class T { };
struct B {
   ~B();
};

void h() {
   B b;
   new (&b) T;
}                                // undefined behavior at block exit
```

— *end example*]

1

Creating a new object at the storage location that a `const` object with static, thread, or automatic storage duration occupies or, at the storage location that such a `const` object used to occupy before its lifetime ended results in undefined behavior. [*Example:*

```
struct B {
  B();
  ~B();
```

41) That is, an object for which a destructor will be called implicitly—upon exit from the block for an object with automatic storage duration, upon exit from the thread for an object with thread storage duration, or upon exit from the program for an object with static storage duration.

```
};

const B b;

void h() {
  b.~B();
  new (const_cast<B*>(&b)) const B;          // undefined behavior
}
```

— *end example*]

1 In this section, "before" and "after" refer to the "happens before" relation (1.859). [*Note:* Therefore, undefined behavior results if an object that is being constructed in one thread is referenced from another thread without adequate synchronization. — *end note*]

3.2955 Types [basic.types]

1

[*Note:* 3.2955 and the subclauses thereof impose requirements on implementations regarding the representation of types. There are two kinds of types: fundamental types and compound types. Types describe objects (1.319), references (8.97.1), or functions (8.360.1). — *end note*]

1

For any object (other than a base-class subobject) of trivially copyable type `T`, whether or not the object holds a valid value of type `T`, the underlying bytes (1.277) making up the object can be copied into an array of `char` or `unsigned char`.[42] If the content of the array of `char` or `unsigned char` is copied back into the object, the object shall subsequently hold its original value. [*Example:*

```
#define N sizeof(T)
char buf[N];
T obj;                          // obj initialized to its original value
std::memcpy(buf, &obj, N);      // between these two calls to std::memcpy,
                                // obj might be modified
std::memcpy(&obj, buf, N);      // at this point, each subobject of obj of scalar type
                                // holds its original value
```

— *end example*]

1

For any trivially copyable type `T`, if two pointers to `T` point to distinct `T` objects `obj1` and `obj2`, where neither `obj1` nor `obj2` is a base-class subobject, if the underlying bytes (1.277) making up `obj1` are copied into `obj2`,[43] `obj2` shall subsequently hold the same value as `obj1`. [*Example:*

```
T* t1p;
T* t2p;
    // provided that t2p points to an initialized object ...
std::memcpy(t1p, t2p, sizeof(T));
    // at this point, every subobject of trivially copyable type in *t1p contains
    // the same value as the corresponding subobject in *t2p
```

— *end example*]

1

42) By using, for example, the library functions (17.48.0.1) `std::memcpy` or `std::memmove`.
43) By using, for example, the library functions (17.48.0.1) `std::memcpy` or `std::memmove`.

The *object representation* of an object of type `T` is the sequence of N `unsigned char` objects taken up by the object of type `T`, where N equals `sizeof(T)`. The *value representation* of an object is the set of bits that hold the value of type `T`. For trivially copyable types, the value representation is a set of bits in the object representation that determines a *value*, which is one discrete element of an implementation-defined set of values.[44]

1

A class that has been declared but not defined, an enumeration type in certain contexts (7.1001), or an array of unknown size or of incomplete element type, is an *incompletely-defined object type*.[45] Incompletely-defined object types and the void types are *incomplete types* (3.3151.1). Objects shall not be defined to have an incomplete type.

1

A class type (such as "`class X`") might be incomplete at one point in a translation unit and complete later on; the type "`class X`" is the same type at both points. The declared type of an array object might be an array of incomplete class type and therefore incomplete; if the class type is completed later on in the translation unit, the array type becomes complete; the array type at those two points is the same type. The declared type of an array object might be an array of unknown size and therefore be incomplete at one point in a translation unit and complete later on; the array types at those two points ("array of unknown bound of `T`" and "array of `N T`") are different types. The type of a pointer to array of unknown size, or of a type defined by a `typedef` declaration to be an array of unknown size, cannot be completed. [*Example:*

```
class X;                        // X is an incomplete type
extern X* xp;                   // xp is a pointer to an incomplete type
extern int arr[];               // the type of arr is incomplete
typedef int UNKA[];             // UNKA is an incomplete type
UNKA* arrp;                     // arrp is a pointer to an incomplete type
UNKA** arrpp;

void foo() {
  xp++;                         // ill-formed: X is incomplete
  arrp++;                       // ill-formed: incomplete type
  arrpp++;                      // OK: sizeof UNKA* is known
}

struct X { int i; };            // now X is a complete type
int  arr[10];                   // now the type of arr is complete

X x;
void bar() {
  xp = &x;                      // OK; type is "pointer to X"
  arrp = &arr;                  // ill-formed: different types
  xp++;                         // OK: X is complete
  arrp++;                       // ill-formed: UNKA can't be completed
}
```

— *end example*]

1 [*Note:* The rules for declarations and expressions describe in which contexts incomplete types are prohibited. — *end note*]

2

44) The intent is that the memory model of C++ is compatible with that of ISO/IEC 9899 Programming Language C.
45) The size and layout of an instance of an incompletely-defined object type is unknown.

An *object type* is a (possibly cv-qualified) type that is not a function type, not a reference type, and not a void type.

1

Arithmetic types (3.3151.1), enumeration types, pointer types, pointer to member types (3.3568.1), `std::nullptr_t`, and cv-qualified versions of these types (3.3640.1) are collectively called *scalar types*. Scalar types, POD classes (Clause 9), arrays of such types and *cv-qualified* versions of these types (3.3640.1) are collectively called *POD types*. Cv-unqualified scalar types, trivially copyable class types (Clause 9), arrays of such types, and non-volatile const-qualified versions of these types (3.3640.1) are collectively called *trivially copyable types*. Scalar types, trivial class types (Clause 9), arrays of such types and cv-qualified versions of these types (3.3640.1) are collectively called *trivial types*. Scalar types, standard-layout class types (Clause 9), arrays of such types and cv-qualified versions of these types (3.3640.1) are collectively called *standard-layout types*.

1

A type is a *literal type* if it is:

— `void`; or

— a scalar type; or

— a reference type; or

— an array of literal type; or

— a class type (Clause 9) that has all of the following properties:

  — it has a trivial destructor,

  — it is an aggregate type (8.1817.1) or has at least one `constexpr` constructor or constructor template that is not a copy or move constructor, and

  — all of its non-static data members and base classes are of non-volatile literal types.

1

If two types `T1` and `T2` are the same type, then `T1` and `T2` are *layout-compatible* types. [*Note:* Layout-compatible enumerations are described in 7.1001. Layout-compatible standard-layout structs and standard-layout unions are described in 9.194. — *end note*]

3.3151.1 Fundamental types [basic.fundamental]

1

Objects declared as characters (`char`) shall be large enough to store any member of the implementation's basic character set. If a character from this set is stored in a character object, the integral value of that character object is equal to the value of the single character literal form of that character. It is implementation-defined whether a `char` object can hold negative values. Characters can be explicitly declared `unsigned` or `signed`. Plain `char`, `signed char`, and `unsigned char` are three distinct types, collectively called *narrow character types*. A `char`, a `signed char`, and an `unsigned char` occupy the same amount of storage and have the same alignment requirements (3.3924); that is, they have the same object representation. For narrow character types, all bits of the object representation participate in the value representation. For unsigned narrow character types, all possible bit patterns of the value representation represent numbers. These requirements do not hold for other types. In any particular implementation, a plain `char` object can take on either the same values as a `signed char` or an `unsigned char`; which one is implementation-defined. For each value i of type `unsigned char` in the range 0 to 255 inclusive, there exists a value j of type `char` such that the result of an integral conversion (4.397) from i to `char` is j, and the result of an integral conversion from j to `unsigned char` is i.

1

There are five *standard signed integer types* : "`signed char`", "`short int`", "`int`", "`long int`", and "`long long int`". In this list, each type provides at least as much storage as those preceding it in the list. There may also be implementation-defined *extended signed integer types*. The standard and extended signed integer types are collectively called *signed integer types*. Plain `int`s have the natural size suggested by the architecture of the execution environment[46]; the other signed integer types are provided to meet special needs.

1

For each of the standard signed integer types, there exists a corresponding (but different) *standard unsigned integer type*: "`unsigned char`", "`unsigned short int`", "`unsigned int`", "`unsigned long int`", and "`unsigned long long int`", each of which occupies the same amount of storage and has the same alignment requirements (3.3924) as the corresponding signed integer type[47]; that is, each signed integer type has the same object representation as its corresponding unsigned integer type. Likewise, for each of the extended signed integer types there exists a corresponding *extended unsigned integer type* with the same amount of storage and alignment requirements. The standard and extended unsigned integer types are collectively called *unsigned integer types*. The range of non-negative values of a *signed integer* type is a subrange of the corresponding *unsigned integer* type, and the value representation of each corresponding signed/unsigned type shall be the same. The standard signed integer types and standard unsigned integer types are collectively called the *standard integer types*, and the extended signed integer types and extended unsigned integer types are collectively called the *extended integer types*. The signed and unsigned integer types shall satisfy the constraints given in the C standard, section 5.2.4.2.1.

1

Unsigned integers shall obey the laws of arithmetic modulo 2^n where n is the number of bits in the value representation of that particular size of integer.[48]

1

Type `wchar_t` is a distinct type whose values can represent distinct codes for all members of the largest extended character set specified among the supported locales (22.3.1). Type `wchar_t` shall have the same size, signedness, and alignment requirements (3.3924) as one of the other integral types, called its *underlying type*. Types `char16_t` and `char32_t` denote distinct types with the same size, signedness, and alignment as `uint_least16_t` and `uint_least32_t`, respectively, in `<cstdint>`, called the underlying types.

1

Values of type `bool` are either `true` or `false`.[49] [*Note:* There are no `signed`, `unsigned`, `short`, or `long bool` types or values. — *end note*] Values of type `bool` participate in integral promotions (4.262).

1

Types `bool`, `char`, `char16_t`, `char32_t`, `wchar_t`, and the signed and unsigned integer types are collectively called *integral* types.[50] A synonym for integral type is *integer type*. The representations of integral types shall define values by use of a pure binary numeration system.[51] [*Example:* this International Standard

46) that is, large enough to contain any value in the range of `INT_MIN` and `INT_MAX`, as defined in the header `<climits>`.

47) See 7.678.0.1 regarding the correspondence between types and the sequences of *type-specifier*s that designate them.

48) This implies that unsigned arithmetic does not overflow because a result that cannot be represented by the resulting unsigned integer type is reduced modulo the number that is one greater than the largest value that can be represented by the resulting unsigned integer type.

49) Using a `bool` value in ways described by this International Standard as "undefined," such as by examining the value of an uninitialized automatic object, might cause it to behave as if it is neither `true` nor `false`.

50) Therefore, enumerations (7.1001) are not integral; however, enumerations can be promoted to integral types as specified in 4.262.

51) A positional representation for integers that uses the binary digits 0 and 1, in which the values represented by successive bits are additive, begin with 1, and are multiplied by successive integral power of 2, except perhaps for the bit with the highest

permits 2's complement, 1's complement and signed magnitude representations for integral types. — *end example*]

1

There are three *floating point* types: `float`, `double`, and `long double`. The type `double` provides at least as much precision as `float`, and the type `long double` provides at least as much precision as `double`. The set of values of the type `float` is a subset of the set of values of the type `double`; the set of values of the type `double` is a subset of the set of values of the type `long double`. The value representation of floating-point types is implementation-defined. *Integral* and *floating* types are collectively called *arithmetic* types. Specializations of the standard template `std::numeric_limits` (18.41) shall specify the maximum and minimum values of each arithmetic type for an implementation.

1

The `void` type has an empty set of values. The `void` type is an incomplete type that cannot be completed. It is used as the return type for functions that do not return a value. Any expression can be explicitly converted to type *cv* `void` (5.2765). An expression of type `void` shall be used only as an expression statement (6.9), as an operand of a comma expression (5.3602), as a second or third operand of `?:` (5.3337), as the operand of `typeid`, `noexcept`, or `decltype`, as the expression in a return statement (6.270.2) for a function with the return type `void`, or as the operand of an explicit conversion to type *cv* `void`.

1 A value of type `std::nullptr_t` is a null pointer constant (4.579). Such values participate in the pointer and the pointer to member conversions (4.579, 4.710). `sizeof(std::nullptr_t)` shall be equal to `sizeof(void*)`.

2

[*Note:* Even if the implementation defines two or more basic types to have the same value representation, they are nevertheless different types. — *end note*]

3.3568.1 Compound types [basic.compound]

1

Compound types can be constructed in the following ways:

— *arrays* of objects of a given type, 8.251.1;

— *functions*, which have parameters of given types and return `void` or references or objects of a given type, 8.360.1;

— *pointers* to `void` or objects or functions (including static members of classes) of a given type, 8.94.1;

— *references* to objects or functions of a given type, 8.97.1. There are two types of references:

  — *lvalue reference*

  — *rvalue reference*

— *classes* containing a sequence of objects of various types (Clause 9), a set of types, enumerations and functions for manipulating these objects (9.401), and a set of restrictions on the access to these entities (Clause 11);

— *unions*, which are classes capable of containing objects of different types at different times, 9.815;

— *enumerations*, which comprise a set of named constant values. Each distinct enumeration constitutes a different *enumerated type*, 7.1001;

position. (Adapted from the *American National Dictionary for Information Processing Systems*.)

— *pointers to non-static* [52] *class members*, which identify members of a given type within objects of a given class, 8.236.1.

1

These methods of constructing types can be applied recursively; restrictions are mentioned in 8.94.1, 8.251.1, 8.360.1, and 8.97.1. Constructing a type such that the number of bytes in its object representation exceeds the maximum value representable in the type `std::size_t` (18.2) is ill-formed.

1

The type of a pointer to `void` or a pointer to an object type is called an *object pointer type*. [*Note:* A pointer to `void` does not have a pointer-to-object type, however, because `void` is not an object type. — *end note*] The type of a pointer that can designate a function is called a *function pointer type*. A pointer to objects of type `T` is referred to as a "pointer to `T`." [*Example:* a pointer to an object of type `int` is referred to as "pointer to `int` " and a pointer to an object of class `X` is called a "pointer to `X`." — *end example*] Except for pointers to static members, text referring to "pointers" does not apply to pointers to members. Pointers to incomplete types are allowed although there are restrictions on what can be done with them (3.3924). A valid value of an object pointer type represents either the address of a byte in memory (1.277) or a null pointer (4.579). If an object of type `T` is located at an address `A`, a pointer of type *cv* `T*` whose value is the address `A` is said to *point to* that object, regardless of how the value was obtained. [*Note:* For instance, the address one past the end of an array (5.2882) would be considered to point to an unrelated object of the array's element type that might be located at that address. There are further restrictions on pointers to objects with dynamic storage duration; see 3.2532.0.1. — *end note*] The value representation of pointer types is implementation-defined. Pointers to cv-qualified and cv-unqualified versions (3.3640.1) of layout-compatible types shall have the same value representation and alignment requirements (3.3924). [*Note:* Pointers to over-aligned types (3.3924) have no special representation, but their range of valid values is restricted by the extended alignment requirement. This International Standard specifies only two ways of obtaining such a pointer: taking the address of a valid object with an over-aligned type, and using one of the runtime pointer alignment functions. An implementation may provide other means of obtaining a valid pointer value for an over-aligned type. — *end note*]

1

A pointer to *cv*-qualified (3.3640.1) or *cv*-unqualified `void` can be used to point to objects of unknown type. Such a pointer shall be able to hold any object pointer. An object of type *cv* `void*` shall have the same representation and alignment requirements as *cv* `char*`.

3.3640.1 CV-qualifiers [basic.type.qualifier]

1

A type mentioned in 3.3151.1 and 3.3568.1 is a *cv-unqualified type*. Each type which is a cv-unqualified complete or incomplete object type or is `void` (3.2955) has three corresponding cv-qualified versions of its type: a *const-qualified* version, a *volatile-qualified* version, and a *const-volatile-qualified* version. The term *object type* (1.319) includes the cv-qualifiers specified in the *decl-specifier-seq* (7.40), *declarator* (Clause 8), *type-id* (8.32), or *new-type-id* (5.2221.1) when the object is created.

— A *const object* is an object of type `const T` or a non-mutable subobject of such an object.

— A *volatile object* is an object of type `volatile T`, a subobject of such an object, or a mutable subobject of a const volatile object.

— A *const volatile object* is an object of type `const volatile T`, a non-mutable subobject of such an object, a const subobject of a volatile object, or a non-mutable volatile subobject of a const object.

52) Static class members are objects or functions, and pointers to them are ordinary pointers to objects or functions.

The cv-qualified or cv-unqualified versions of a type are distinct types; however, they shall have the same representation and alignment requirements (3.3924).[53]

1

A compound type (3.3568.1) is not cv-qualified by the cv-qualifiers (if any) of the types from which it is compounded. Any cv-qualifiers applied to an array type affect the array element type, not the array type (8.251.1).

1 See 8.360.1 and 9.508.1 regarding function types that have *cv-qualifier*s.

2

There is a partial ordering on cv-qualifiers, so that a type can be said to be *more cv-qualified* than another. Table 9 shows the relations that constitute this ordering.

Table 9 — Relations on `const` and `volatile`

no cv-qualifier	<	`const`
no cv-qualifier	<	`volatile`
no cv-qualifier	<	`const volatile`
`const`	<	`const volatile`
`volatile`	<	`const volatile`

1

In this International Standard, the notation *cv* (or *cv1*, *cv2*, etc.), used in the description of types, represents an arbitrary set of cv-qualifiers, i.e., one of {`const`}, {`volatile`}, {`const`, `volatile`}, or the empty set. Cv-qualifiers applied to an array type attach to the underlying element type, so the notation "*cv* `T`," where `T` is an array type, refers to an array whose elements are so-qualified. An array type whose elements are cv-qualified is also considered to have the same cv-qualifications as its elements. [*Example:*

```
typedef char CA[5];
typedef const char CC;
CC arr1[5] = { 0 };
const CA arr2 = { 0 };
```

The type of both `arr1` and `arr2` is "array of 5 `const char`," and the array type is considered to be `const`-qualified. — *end example*]

3.3673 Lvalues and rvalues [basic.lval]

1

Expressions are categorized according to the taxonomy in Figure 1.

— An *lvalue* (so called, historically, because lvalues could appear on the left-hand side of an assignment expression) designates a function or an object. [*Example:* If `E` is an expression of pointer type, then `*E` is an lvalue expression referring to the object or function to which `E` points. As another example, the result of calling a function whose return type is an lvalue reference is an lvalue. — *end example*]

— An *xvalue* (an "eXpiring" value) also refers to an object, usually near the end of its lifetime (so that its resources may be moved, for example). An xvalue is the result of certain kinds of expressions involving rvalue references (8.97.1). [*Example:* The result of calling a function whose return type is an rvalue reference to an object type is an xvalue (5.955.1). — *end example*]

— A *glvalue* ("generalized" lvalue) is an lvalue or an xvalue.

53) The same representation and alignment requirements are meant to imply interchangeability as arguments to functions, return values from functions, and non-static data members of unions.

Figure 1 — Expression category taxonomy

— An *rvalue* (so called, historically, because rvalues could appear on the right-hand side of an assignment expression) is an xvalue, a temporary object (12.306) or subobject thereof, or a value that is not associated with an object.

— A *prvalue* ("pure" rvalue) is an rvalue that is not an xvalue. [*Example:* The result of calling a function whose return type is not a reference is a prvalue. The value of a literal such as `12`, `7.3e5`, or `true` is also a prvalue. — *end example*]

Every expression belongs to exactly one of the fundamental classifications in this taxonomy: lvalue, xvalue, or prvalue. This property of an expression is called its *value category*. [*Note:* The discussion of each built-in operator in Clause 5 indicates the category of the value it yields and the value categories of the operands it expects. For example, the built-in assignment operators expect that the left operand is an lvalue and that the right operand is a prvalue and yield an lvalue as the result. User-defined operators are functions, and the categories of values they expect and yield are determined by their parameter and return types. — *end note*]

1

Whenever a glvalue appears in a context where a prvalue is expected, the glvalue is converted to a prvalue; see 4.127, 4.180, and 4.220. [*Note:* An attempt to bind an rvalue reference to an lvalue is not such a context; see 8.2156.1. — *end note*]

1

The discussion of reference initialization in 8.2156.1 and of temporaries in 12.306 indicates the behavior of lvalues and rvalues in other significant contexts.

1

Unless otherwise indicated (5.955.1), prvalues shall always have complete types or the `void` type; in addition to these types, glvalues can also have incomplete types. [*Note:* class and array prvalues can have cv-qualified types; other prvalues always have cv-unqualified types. See Clause 5. — *end note*]

1

An lvalue for an object is necessary in order to modify the object except that an rvalue of class type can also be used to modify its referent under certain circumstances. [*Example:* a member function called for an object (9.401) can modify the object. — *end example*]

1

Functions cannot be modified, but pointers to functions can be modifiable.

1

A pointer to an incomplete type can be modifiable. At some point in the program when the pointed to type is complete, the object at which the pointer points can also be modified.

1

The referent of a `const`-qualified expression shall not be modified (through that expression), except that if it is of class type and has a `mutable` component, that component can be modified (7.567.0.1).

1

If an expression can be used to modify the object to which it refers, the expression is called *modifiable*. A program that attempts to modify an object through a nonmodifiable lvalue or rvalue expression is ill-formed.

1

If a program attempts to access the stored value of an object through a glvalue of other than one of the following types the behavior is undefined:[54]

— the dynamic type of the object,

— a cv-qualified version of the dynamic type of the object,

— a type similar (as defined in 4.246) to the dynamic type of the object,

— a type that is the signed or unsigned type corresponding to the dynamic type of the object,

— a type that is the signed or unsigned type corresponding to a cv-qualified version of the dynamic type of the object,

— an aggregate or union type that includes one of the aforementioned types among its elements or non-static data members (including, recursively, an element or non-static data member of a subaggregate or contained union),

— a type that is a (possibly cv-qualified) base class type of the dynamic type of the object,

— a `char` or `unsigned char` type.

3.3924 Alignment [basic.align]

1

Object types have *alignment requirements* (3.3151.1, 3.3568.1) which place restrictions on the addresses at which an object of that type may be allocated. An *alignment* is an implementation-defined integer value representing the number of bytes between successive addresses at which a given object can be allocated. An object type imposes an alignment requirement on every object of that type; stricter alignment can be requested using the alignment specifier (7.1556.1).

1

A *fundamental alignment* is represented by an alignment less than or equal to the greatest alignment supported by the implementation in all contexts, which is equal to `alignof(std::max_align_t)` (18.2). The alignment required for a type might be different when it is used as the type of a complete object and when it is used as the type of a subobject. [*Example:*

```
struct B { long double d; };
struct D : virtual B { char c; }
```

When `D` is the type of a complete object, it will have a subobject of type `B`, so it must be aligned appropriately for a `long double`. If `D` appears as a subobject of another object that also has `B` as a virtual base class, the `B` subobject might be part of a different subobject, reducing the alignment requirements on the `D` subobject. — *end example*] The result of the `alignof` operator reflects the alignment requirement of the type in the complete-object case.

54) The intent of this list is to specify those circumstances in which an object may or may not be aliased.

1

An *extended alignment* is represented by an alignment greater than `alignof(std::max_align_t)`. It is implementation-defined whether any extended alignments are supported and the contexts in which they are supported (7.1556.1). A type having an extended alignment requirement is an *over-aligned type*. [*Note:* every over-aligned type is or contains a class type to which extended alignment applies (possibly through a non-static data member). — *end note*]

1

Alignments are represented as values of the type `std::size_t`. Valid alignments include only those values returned by an `alignof` expression for the fundamental types plus an additional implementation-defined set of values, which may be empty. Every alignment value shall be a non-negative integral power of two.

1

Alignments have an order from *weaker* to *stronger* or *stricter* alignments. Stricter alignments have larger alignment values. An address that satisfies an alignment requirement also satisfies any weaker valid alignment requirement.

1

The alignment requirement of a complete type can be queried using an `alignof` expression (5.2747.1). Furthermore, the narrow character types (3.3151.1) shall have the weakest alignment requirement. [*Note:* This enables the narrow character types to be used as the underlying type for an aligned memory area (7.1556.1). — *end note*]

1

Comparing alignments is meaningful and provides the obvious results:

— Two alignments are equal when their numeric values are equal.

— Two alignments are different when their numeric values are not equal.

— When an alignment is larger than another it represents a stricter alignment.

1 [*Note:* The runtime pointer alignment function (20.85.2) can be used to obtain an aligned pointer within a buffer; the aligned-storage templates in the library (20.570.1.6) can be used to obtain aligned storage. — *end note*]

2

If a request for a specific extended alignment in a specific context is not supported by an implementation, the program is ill-formed. Additionally, a request for runtime allocation of dynamic storage for which the requested alignment cannot be honored shall be treated as an allocation failure.

4 Standard conversions [conv]

1

Standard conversions are implicit conversions with built-in meaning. Clause 4 enumerates the full set of such conversions. A *standard conversion sequence* is a sequence of standard conversions in the following order:

— Zero or one conversion from the following set: lvalue-to-rvalue conversion, array-to-pointer conversion, and function-to-pointer conversion.

— Zero or one conversion from the following set: integral promotions, floating point promotion, integral conversions, floating point conversions, floating-integral conversions, pointer conversions, pointer to member conversions, and boolean conversions.

— Zero or one qualification conversion.

[*Note:* A standard conversion sequence can be empty, i.e., it can consist of no conversions. — *end note*] A standard conversion sequence will be applied to an expression if necessary to convert it to a required destination type.

1

[*Note:* expressions with a given type will be implicitly converted to other types in several contexts:

— When used as operands of operators. The operator's requirements for its operands dictate the destination type (Clause 5).

— When used in the condition of an `if` statement or iteration statement (6.23, 6.137). The destination type is `bool`.

— When used in the expression of a `switch` statement. The destination type is integral (6.23).

— When used as the source expression for an initialization (which includes use as an argument in a function call and use as the expression in a `return` statement). The type of the entity being initialized is (generally) the destination type. See 8.821, 8.2156.1.

— *end note*]

1

An expression `e` can be *implicitly converted* to a type `T` if and only if the declaration `T t=e;` is well-formed, for some invented temporary variable `t` (8.821).

1

Certain language constructs require that an expression be converted to a Boolean value. An expression `e` appearing in such a context is said to be *contextually converted to* `bool` and is well-formed if and only if the declaration `bool t(e);` is well-formed, for some invented temporary variable `t` (8.821).

1

Certain language constructs require conversion to a value having one of a specified set of types appropriate to the construct. An expression `e` of class type `E` appearing in such a context is said to be *contextually implicitly converted to* a specified type `T` and is well-formed if and only if `e` can be implicitly converted to a type `T` that is determined as follows: `E` is searched for conversion functions whose return type is *cv* `T` or reference to *cv* `T` such that `T` is allowed by the context. There shall be exactly one such `T`.

1

The effect of any implicit conversion is the same as performing the corresponding declaration and initialization and then using the temporary variable as the result of the conversion. The result is an lvalue if `T` is an lvalue reference type or an rvalue reference to function type (8.97.1), an xvalue if `T` is an rvalue reference to object type, and a prvalue otherwise. The expression `e` is used as a glvalue if and only if the initialization uses it as a glvalue.

1

[*Note:* For class types, user-defined conversions are considered as well; see 12.659. In general, an implicit conversion sequence (13.779.0.1) consists of a standard conversion sequence followed by a user-defined conversion followed by another standard conversion sequence. — *end note*]

1

[*Note:* There are some contexts where certain conversions are suppressed. For example, the lvalue-to-rvalue conversion is not done on the operand of the unary `&` operator. Specific exceptions are given in the descriptions of those operators and contexts. — *end note*]

4.127 Lvalue-to-rvalue conversion [conv.lval]

1

A glvalue (3.3673) of a non-function, non-array type `T` can be converted to a prvalue.[55] If `T` is an incomplete type, a program that necessitates this conversion is ill-formed. If `T` is a non-class type, the type of the prvalue is the cv-unqualified version of `T`. Otherwise, the type of the prvalue is `T`.[56]

1

When an lvalue-to-rvalue conversion is applied to an expression `e`, and either

— `e` is not potentially evaluated, or

— the evaluation of `e` results in the evaluation of a member `ex` of the set of potential results of `e`, and `ex` names a variable `x` that is not odr-used by `ex` (3.91),

the value contained in the referenced object is not accessed. [*Example:*

```
struct S { int n; };
auto f() {
  S x { 1 };
  constexpr S y { 2 };
  return [&](bool b) { return (b ? y : x).n; };
}
auto g = f();
int m = g(false); // undefined behavior due to access of x.n outside its lifetime
int n = g(true);  // OK, does not access y.n
```

— *end example*] In all other cases, the result of the conversion is determined according to the following rules:

— If `T` is (possibly cv-qualified) `std::nullptr_t`, the result is a null pointer constant (4.579).

— Otherwise, if `T` has a class type, the conversion copy-initializes a temporary of type `T` from the glvalue and the result of the conversion is a prvalue for the temporary.

55) For historical reasons, this conversion is called the "lvalue-to-rvalue" conversion, even though that name does not accurately reflect the taxonomy of expressions described in 3.3673.

56) In C++ class prvalues can have cv-qualified types (because they are objects). This differs from ISO C, in which non-lvalues never have cv-qualified types.

— Otherwise, if the object to which the glvalue refers contains an invalid pointer value (3.2428.0.1, 3.2532.0.1), the behavior is implementation-defined.

— Otherwise, the value contained in the object indicated by the glvalue is the prvalue result.

1 [*Note:* See also 3.3673. — *end note*]

4.180 Array-to-pointer conversion [conv.array]

1

An lvalue or rvalue of type "array of `N T`" or "array of unknown bound of `T`" can be converted to a prvalue of type "pointer to `T`". The result is a pointer to the first element of the array.

4.220 Function-to-pointer conversion [conv.func]

1

An lvalue of function type `T` can be converted to a prvalue of type "pointer to `T`." The result is a pointer to the function.[57]

1 [*Note:* See 13.1084 for additional rules for the case where the function is overloaded. — *end note*]

4.246 Qualification conversions [conv.qual]

1

A prvalue of type "pointer to *cv1* `T`" can be converted to a prvalue of type "pointer to *cv2* `T`" if "*cv2* `T`" is more cv-qualified than "*cv1* `T`".

1 A prvalue of type "pointer to member of `X` of type *cv1* `T`" can be converted to a prvalue of type "pointer to member of `X` of type *cv2* `T`" if "*cv2* `T`" is more cv-qualified than "*cv1* `T`".

2

[*Note:* Function types (including those used in pointer to member function types) are never cv-qualified (8.360.1). — *end note*]

1

A conversion can add cv-qualifiers at levels other than the first in multi-level pointers, subject to the following rules:[58]

> Two pointer types T1 and T2 are *similar* if there exists a type T and integer $n > 0$ such that:
>
> *T1* is $cv_{1,0}$ pointer to $cv_{1,1}$ pointer to $\cdots$ $cv_{1,n-1}$ pointer to $cv_{1,n}$ T
>
> and
>
> *T2* is $cv_{2,0}$ pointer to $cv_{2,1}$ pointer to $\cdots$ $cv_{2,n-1}$ pointer to $cv_{2,n}$ T
>
> where each $cv_{i,j}$ is `const`, `volatile`, `const volatile`, or nothing. The n-tuple of cv-qualifiers after the first in a pointer type, e.g., $cv_{1,1}$, $cv_{1,2}$, $\cdots$, $cv_{1,n}$ in the pointer type *T1*, is called the *cv-qualification signature* of the pointer type. An expression of type *T1* can be converted to type *T2* if and only if the following conditions are satisfied:
>
> — the pointer types are similar.
>
> — for every $j > 0$, if `const` is in $cv_{1,j}$ then `const` is in $cv_{2,j}$, and similarly for `volatile`.
>
> — if the $cv_{1,j}$ and $cv_{2,j}$ are different, then `const` is in every $cv_{2,k}$ for $0 < k < j$.

57) This conversion never applies to non-static member functions because an lvalue that refers to a non-static member function cannot be obtained.

58) These rules ensure that const-safety is preserved by the conversion.

[*Note:* if a program could assign a pointer of type `T**` to a pointer of type `const T**` (that is, if line `#1` below were allowed), a program could inadvertently modify a `const` object (as it is done on line `#2`). For example,

```
int main() {
  const char c = 'c';
  char* pc;
  const char** pcc = &pc;        // #1: not allowed
  *pcc = &c;
  *pc = 'C';                     // #2: modifies a const object
}
```

— *end note*]

1 A *multi-level* pointer to member type, or a *multi-level mixed* pointer and pointer to member type has the form:

$$cv_0 P_0 \text{ to } cv_1 P_1 \text{ to } \cdots\ cv_{n-1} P_{n-1} \text{ to } cv_n\ T$$

where P_i is either a pointer or pointer to member and where T is not a pointer type or pointer to member type.

2 Two multi-level pointer to member types or two multi-level mixed pointer and pointer to member types T1 and T2 are *similar* if there exists a type T and integer $n > 0$ such that:

$$T1 \text{ is } cv_{1,0} P_0 \text{ to } cv_{1,1} P_1 \text{ to } \cdots\ cv_{1,n-1} P_{n-1} \text{ to } cv_{1,n}\ T$$

and

$$T2 \text{ is } cv_{2,0} P_0 \text{ to } cv_{2,1} P_1 \text{ to } \cdots\ cv_{2,n-1} P_{n-1} \text{ to } cv_{2,n}\ T$$

3 For similar multi-level pointer to member types and similar multi-level mixed pointer and pointer to member types, the rules for adding cv-qualifiers are the same as those used for similar pointer types.

4.262 Integral promotions [conv.prom]

1

A prvalue of an integer type other than `bool`, `char16_t`, `char32_t`, or `wchar_t` whose integer conversion rank (4.807) is less than the rank of `int` can be converted to a prvalue of type `int` if `int` can represent all the values of the source type; otherwise, the source prvalue can be converted to a prvalue of type `unsigned int`.

1

A prvalue of type `char16_t`, `char32_t`, or `wchar_t` (3.3151.1) can be converted to a prvalue of the first of the following types that can represent all the values of its underlying type: `int`, `unsigned int`, `long int`, `unsigned long int`, `long long int`, or `unsigned long long int`. If none of the types in that list can represent all the values of its underlying type, a prvalue of type `char16_t`, `char32_t`, or `wchar_t` can be converted to a prvalue of its underlying type.

1

A prvalue of an unscoped enumeration type whose underlying type is not fixed (7.1001) can be converted to a prvalue of the first of the following types that can represent all the values of the enumeration (i.e., the values in the range b_{min} to b_{max} as described in 7.1001): `int`, `unsigned int`, `long int`, `unsigned long int`, `long long int`, or `unsigned long long int`. If none of the types in that list can represent all the values of the enumeration, a prvalue of an unscoped enumeration type can be converted to a prvalue of the extended integer type with lowest integer conversion rank (4.807) greater than the rank of `long long` in which all the values of the enumeration can be represented. If there are two such extended types, the signed one is chosen.

1

A prvalue of an unscoped enumeration type whose underlying type is fixed (7.1001) can be converted to a prvalue of its underlying type. Moreover, if integral promotion can be applied to its underlying type, a prvalue of an unscoped enumeration type whose underlying type is fixed can also be converted to a prvalue of the promoted underlying type.

1

A prvalue for an integral bit-field (9.921) can be converted to a prvalue of type `int` if `int` can represent all the values of the bit-field; otherwise, it can be converted to `unsigned int` if `unsigned int` can represent all the values of the bit-field. If the bit-field is larger yet, no integral promotion applies to it. If the bit-field has an enumerated type, it is treated as any other value of that type for promotion purposes.

1

A prvalue of type `bool` can be converted to a prvalue of type `int`, with `false` becoming zero and `true` becoming one.

1 These conversions are called *integral promotions*.

4.389 Floating point promotion [conv.fpprom]

1

A prvalue of type `float` can be converted to a prvalue of type `double`. The value is unchanged.

1 This conversion is called *floating point promotion*.

4.397 Integral conversions [conv.integral]

1

A prvalue of an integer type can be converted to a prvalue of another integer type. A prvalue of an unscoped enumeration type can be converted to a prvalue of an integer type.

1

If the destination type is unsigned, the resulting value is the least unsigned integer congruent to the source integer (modulo 2^n where n is the number of bits used to represent the unsigned type). [*Note:* In a two's complement representation, this conversion is conceptual and there is no change in the bit pattern (if there is no truncation). — *end note*]

1

If the destination type is signed, the value is unchanged if it can be represented in the destination type (and bit-field width); otherwise, the value is implementation-defined.

1

If the destination type is `bool`, see 4.732. If the source type is `bool`, the value `false` is converted to zero and the value `true` is converted to one.

1

The conversions allowed as integral promotions are excluded from the set of integral conversions.

4.516 Floating point conversions [conv.double]

1

A prvalue of floating point type can be converted to a prvalue of another floating point type. If the source value can be exactly represented in the destination type, the result of the conversion is that exact representation. If the source value is between two adjacent destination values, the result of the conversion is an implementation-defined choice of either of those values. Otherwise, the behavior is undefined.

1

The conversions allowed as floating point promotions are excluded from the set of floating point conversions.

4.532 Floating-integral conversions [conv.fpint]

1

A prvalue of a floating point type can be converted to a prvalue of an integer type. The conversion truncates; that is, the fractional part is discarded. The behavior is undefined if the truncated value cannot be represented in the destination type. [*Note:* If the destination type is `bool`, see 4.732. — *end note*]

1

A prvalue of an integer type or of an unscoped enumeration type can be converted to a prvalue of a floating point type. The result is exact if possible. If the value being converted is in the range of values that can be represented but the value cannot be represented exactly, it is an implementation-defined choice of either the next lower or higher representable value. [*Note:* Loss of precision occurs if the integral value cannot be represented exactly as a value of the floating type. — *end note*] If the value being converted is outside the range of values that can be represented, the behavior is undefined. If the source type is `bool`, the value `false` is converted to zero and the value `true` is converted to one.

4.579 Pointer conversions [conv.ptr]

1

A *null pointer constant* is an integer literal (2.300.1) with value zero or a prvalue of type `std::nullptr_t`. A null pointer constant can be converted to a pointer type; the result is the *null pointer value* of that type and is distinguishable from every other value of object pointer or function pointer type. Such a conversion is called a *null pointer conversion*. Two null pointer values of the same type shall compare equal. The conversion of a null pointer constant to a pointer to cv-qualified type is a single conversion, and not the sequence of a pointer conversion followed by a qualification conversion (4.246). A null pointer constant of integral type can be converted to a prvalue of type `std::nullptr_t`. [*Note:* The resulting prvalue is not a null pointer value. — *end note*]

1

A prvalue of type "pointer to *cv* `T`," where `T` is an object type, can be converted to a prvalue of type "pointer to *cv* `void`". The result of converting a non-null pointer value of a pointer to object type to a "pointer to *cv* `void`" represents the address of the same byte in memory as the original pointer value. The null pointer value is converted to the null pointer value of the destination type.

1

A prvalue of type "pointer to *cv* `D`", where `D` is a class type, can be converted to a prvalue of type "pointer to *cv* `B`", where `B` is a base class (Clause 10) of `D`. If `B` is an inaccessible (Clause 11) or ambiguous (10.52) base class of `D`, a program that necessitates this conversion is ill-formed. The result of the conversion is a pointer to the base class subobject of the derived class object. The null pointer value is converted to the null pointer value of the destination type.

4.710 Pointer to member conversions [conv.mem]

1

A null pointer constant (4.579) can be converted to a pointer to member type; the result is the *null member pointer value* of that type and is distinguishable from any pointer to member not created from a null pointer constant. Such a conversion is called a *null member pointer conversion*. Two null member pointer values of the same type shall compare equal. The conversion of a null pointer constant to a pointer to member of cv-qualified type is a single conversion, and not the sequence of a pointer to member conversion followed by a qualification conversion (4.246).

1

A prvalue of type "pointer to member of `B` of type *cv* `T`", where `B` is a class type, can be converted to a prvalue of type "pointer to member of `D` of type *cv* `T`", where `D` is a derived class (Clause 10) of `B`. If `B` is an inaccessible (Clause 11), ambiguous (10.52), or virtual (10.31) base class of `D`, or a base class of a virtual base class of `D`, a program that necessitates this conversion is ill-formed. The result of the conversion refers to the same member as the pointer to member before the conversion took place, but it refers to the base class member as if it were a member of the derived class. The result refers to the member in `D`'s instance of `B`. Since the result has type "pointer to member of `D` of type *cv* `T`", indirection through it with a `D` object is valid. The result is the same as if indirecting through the pointer to member of `B` with the `B` subobject of `D`. The null member pointer value is converted to the null member pointer value of the destination type.[59]

4.732 Boolean conversions [conv.bool]

1

A prvalue of arithmetic, unscoped enumeration, pointer, or pointer to member type can be converted to a prvalue of type `bool`. A zero value, null pointer value, or null member pointer value is converted to `false`; any other value is converted to `true`. For direct-initialization (8.821), a prvalue of type `std::nullptr_t` can be converted to a prvalue of type `bool`; the resulting value is `false`.

4.807 Integer conversion rank [conv.rank]

1

Every integer type has an *integer conversion rank* defined as follows:

— No two signed integer types other than `char` and `signed char` (if `char` is signed) shall have the same rank, even if they have the same representation.

— The rank of a signed integer type shall be greater than the rank of any signed integer type with a smaller size.

— The rank of `long long int` shall be greater than the rank of `long int`, which shall be greater than the rank of `int`, which shall be greater than the rank of `short int`, which shall be greater than the rank of `signed char`.

— The rank of any unsigned integer type shall equal the rank of the corresponding signed integer type.

— The rank of any standard integer type shall be greater than the rank of any extended integer type with the same size.

— The rank of `char` shall equal the rank of `signed char` and `unsigned char`.

— The rank of `bool` shall be less than the rank of all other standard integer types.

— The ranks of `char16_t`, `char32_t`, and `wchar_t` shall equal the ranks of their underlying types (3.3151.1).

— The rank of any extended signed integer type relative to another extended signed integer type with the same size is implementation-defined, but still subject to the other rules for determining the integer conversion rank.

— For all integer types `T1`, `T2`, and `T3`, if `T1` has greater rank than `T2` and `T2` has greater rank than `T3`, then `T1` shall have greater rank than `T3`.

59) The rule for conversion of pointers to members (from pointer to member of base to pointer to member of derived) appears inverted compared to the rule for pointers to objects (from pointer to derived to pointer to base) (4.579, Clause 10). This inversion is necessary to ensure type safety. Note that a pointer to member is not an object pointer or a function pointer and the rules for conversions of such pointers do not apply to pointers to members. In particular, a pointer to member cannot be converted to a `void*`.

[*Note:* The integer conversion rank is used in the definition of the integral promotions (4.262) and the usual arithmetic conversions (Clause 5). — *end note*]

5 Expressions [expr]

1

[*Note:* Clause 5 defines the syntax, order of evaluation, and meaning of expressions.[60] An expression is a sequence of operators and operands that specifies a computation. An expression can result in a value and can cause side effects. — *end note*]

1

[*Note:* Operators can be overloaded, that is, given meaning when applied to expressions of class type (Clause 9) or enumeration type (7.1001). Uses of overloaded operators are transformed into function calls as described in 13.1122. Overloaded operators obey the rules for syntax specified in Clause 5, but the requirements of operand type, value category, and evaluation order are replaced by the rules for function call. Relations between operators, such as `++a` meaning `a+=1`, are not guaranteed for overloaded operators (13.1122), and are not guaranteed for operands of type `bool`. — *end note*]

1

Clause 5 defines the effects of operators when applied to types for which they have not been overloaded. Operator overloading shall not modify the rules for the *built-in operators*, that is, for operators applied to types for which they are defined by this Standard. However, these built-in operators participate in overload resolution, and as part of that process user-defined conversions will be considered where necessary to convert the operands to types appropriate for the built-in operator. If a built-in operator is selected, such conversions will be applied to the operands before the operation is considered further according to the rules in Clause 5; see 13.264.0.1, 13.1258.

1

If during the evaluation of an expression, the result is not mathematically defined or not in the range of representable values for its type, the behavior is undefined. [*Note:* most existing implementations of C++ ignore integer overflows. Treatment of division by zero, forming a remainder using a zero divisor, and all floating point exceptions vary among machines, and is usually adjustable by a library function. — *end note*]

1

If an expression initially has the type "reference to `T`" (8.97.1, 8.2156.1), the type is adjusted to `T` prior to any further analysis. The expression designates the object or function denoted by the reference, and the expression is an lvalue or an xvalue, depending on the expression.

1

If a prvalue initially has the type "*cv* `T`," where `T` is a cv-unqualified non-class, non-array type, the type of the expression is adjusted to `T` prior to any further analysis.

1

[*Note:* An expression is an xvalue if it is:

— the result of calling a function, whether implicitly or explicitly, whose return type is an rvalue reference to object type,

— a cast to an rvalue reference to object type,

60) The precedence of operators is not directly specified, but it can be derived from the syntax.

— a class member access expression designating a non-static data member of non-reference type in which the object expression is an xvalue, or

— a `.*` pointer-to-member expression in which the first operand is an xvalue and the second operand is a pointer to data member.

In general, the effect of this rule is that named rvalue references are treated as lvalues and unnamed rvalue references to objects are treated as xvalues; rvalue references to functions are treated as lvalues whether named or not. — *end note*]

[*Example:*

```
struct A {
  int m;
};
A&& operator+(A, A);
A&& f();

A a;
A&& ar = static_cast<A&&>(a);
```

The expressions `f()`, `f().m`, `static_cast<A&&>(a)`, and `a + a` are xvalues. The expression `ar` is an lvalue. — *end example*]

1

In some contexts, *unevaluated operands* appear (5.1393.1, 5.2075.1, 5.2750.1, 7.678.0.1). An unevaluated operand is not evaluated. An unevaluated operand is considered a full-expression. [*Note:* In an unevaluated operand, a non-static class member may be named (5.398) and naming of objects or functions does not, by itself, require that a definition be provided (3.91). — *end note*]

1

Whenever a glvalue expression appears as an operand of an operator that expects a prvalue for that operand, the lvalue-to-rvalue (4.127), array-to-pointer (4.180), or function-to-pointer (4.220) standard conversions are applied to convert the expression to a prvalue. [*Note:* because cv-qualifiers are removed from the type of an expression of non-class type when the expression is converted to a prvalue, an lvalue expression of type `const int` can, for example, be used where a prvalue expression of type `int` is required. — *end note*]

1

Many binary operators that expect operands of arithmetic or enumeration type cause conversions and yield result types in a similar way. The purpose is to yield a common type, which is also the type of the result. This pattern is called the *usual arithmetic conversions*, which are defined as follows:

— If either operand is of scoped enumeration type (7.1001), no conversions are performed; if the other operand does not have the same type, the expression is ill-formed.

— If either operand is of type `long double`, the other shall be converted to `long double`.

— Otherwise, if either operand is `double`, the other shall be converted to `double`.

— Otherwise, if either operand is `float`, the other shall be converted to `float`.

— Otherwise, the integral promotions (4.262) shall be performed on both operands.[61] Then the following rules shall be applied to the promoted operands:

61) As a consequence, operands of type `bool`, `char16_t`, `char32_t`, `wchar_t`, or an enumerated type are converted to some integral type.

— If both operands have the same type, no further conversion is needed.

— Otherwise, if both operands have signed integer types or both have unsigned integer types, the operand with the type of lesser integer conversion rank shall be converted to the type of the operand with greater rank.

— Otherwise, if the operand that has unsigned integer type has rank greater than or equal to the rank of the type of the other operand, the operand with signed integer type shall be converted to the type of the operand with unsigned integer type.

— Otherwise, if the type of the operand with signed integer type can represent all of the values of the type of the operand with unsigned integer type, the operand with unsigned integer type shall be converted to the type of the operand with signed integer type.

— Otherwise, both operands shall be converted to the unsigned integer type corresponding to the type of the operand with signed integer type.

1

In some contexts, an expression only appears for its side effects. Such an expression is called a *discarded-value expression*. The expression is evaluated and its value is discarded. The array-to-pointer (4.180) and function-to-pointer (4.220) standard conversions are not applied. The lvalue-to-rvalue conversion (4.127) is applied if and only if the expression is a glvalue of volatile-qualified type and it is one of the following:

— `(` *expression* `)`, where *expression* is one of these expressions,

— *id-expression* (5.398.1),

— subscripting (5.896.1),

— class member access (5.1194.1),

— indirection (5.1898.1),

— pointer-to-member operation (5.2832),

— conditional expression (5.3337) where both the second and the third operands are one of these expressions, or

— comma expression (5.3602) where the right operand is one of these expressions.

[*Note:* Using an overloaded operator causes a function call; the above covers only operators with built-in meaning. If the lvalue is of class type, it must have a volatile copy constructor to initialize the temporary that is the result of the lvalue-to-rvalue conversion. — *end note*]

1

The values of the floating operands and the results of floating expressions may be represented in greater precision and range than that required by the type; the types are not changed thereby.[62]

1

The *cv-combined type* of two types `T1` and `T2` is a type `T3` similar to `T1` whose cv-qualification signature (4.246) is:

— for every $j > 0$, $cv_{3,j}$ is the union of $cv_{1,j}$ and $cv_{2,j}$;

— if the resulting $cv_{3,j}$ is different from $cv_{1,j}$ or $cv_{2,j}$, then `const` is added to every $cv_{3,k}$ for $0 < k < j$.

62) The cast and assignment operators must still perform their specific conversions as described in 5.2765, 5.1443.1 and 5.3483.

[*Note:* Given similar types `T1` and `T2`, this construction ensures that both can be converted to `T3`. — *end note*] The *composite pointer type* of two operands `p1` and `p2` having types `T1` and `T2`, respectively, where at least one is a pointer or pointer to member type or `std::nullptr_t`, is:

— if both `p1` and `p2` are null pointer constants, `std::nullptr_t`;

— if either `p1` or `p2` is a null pointer constant, `T2` or `T1`, respectively;

— if `T1` or `T2` is "pointer to *cv1* `void`" and the other type is "pointer to *cv2* T", "pointer to *cv12* `void`", where *cv12* is the union of *cv1* and *cv2*;

— if `T1` is "pointer to *cv1* `C1`" and `T2` is "pointer to *cv2* `C2`", where `C1` is reference-related to `C2` or `C2` is reference-related to `C1` (8.2156.1), the cv-combined type of `T1` and `T2` or the cv-combined type of `T2` and `T1`, respectively;

— if `T1` is "pointer to member of `C1` of type *cv1* `U1`" and `T2` is "pointer to member of `C2` of type *cv2* `U2`" where `C1` is reference-related to `C2` or `C2` is reference-related to `C1` (8.2156.1), the cv-combined type of `T2` and `T1` or the cv-combined type of `T1` and `T2`, respectively;

— if `T1` and `T2` are similar multi-level mixed pointer and pointer to member types (4.246), the cv-combined type of `T1` and `T2`;

— otherwise, a program that necessitates the determination of a composite pointer type is ill-formed.

[*Example:*

```
typedef void *p;
typedef const int *q;
typedef int **pi;
typedef const int **pci;
```

The composite pointer type of `p` and `q` is "pointer to `const void`"; the composite pointer type of `pi` and `pci` is "pointer to `const` pointer to `const int`". — *end example*]

5.398 Primary expressions [expr.prim]

5.398.1 General [expr.prim.general]

primary-expression:
- *literal*
- `this`
- `(` *expression* `)`
- *id-expression*
- *lambda-expression*

id-expression:
- *unqualified-id*
- *qualified-id*

unqualified-id:
- *identifier*
- *operator-function-id*
- *conversion-function-id*
- *literal-operator-id*
- `~` *class-name*
- `~` *decltype-specifier*
- *template-id*

1

A *literal* is a primary expression. Its type depends on its form (2.299). A string literal is an lvalue; all other literals are prvalues.

1

The keyword `this` names a pointer to the object for which a non-static member function (9.508.1) is invoked or a non-static data member's initializer (9.194) is evaluated.

1

If a declaration declares a member function or member function template of a class `X`, the expression `this` is a prvalue of type "pointer to *cv-qualifier-seq* `X`" between the optional *cv-qualifer-seq* and the end of the *function-definition*, *member-declarator*, or *declarator*. It shall not appear before the optional *cv-qualifier-seq* and it shall not appear within the declaration of a static member function (although its type and value category are defined within a static member function as they are within a non-static member function). [*Note:* this is because declaration matching does not occur until the complete declarator is known. — *end note*] Unlike the object expression in other contexts, `*this` is not required to be of complete type for purposes of class member access (5.1194.1) outside the member function body. [*Note:* only class members declared prior to the declaration are visible. — *end note*] [*Example:*

```
struct A {
  char g();
  template<class T> auto f(T t) -> decltype(t + g())
    { return t + g(); }
};
template auto A::f(int t) -> decltype(t + g());
```

— *end example*]

1

Otherwise, if a *member-declarator* declares a non-static data member (9.194) of a class `X`, the expression `this` is a prvalue of type "pointer to `X`" within the optional *brace-or-equal-initializer*. It shall not appear elsewhere in the *member-declarator*.

1

The expression `this` shall not appear in any other context. [*Example:*

```
class Outer {
  int a[sizeof(*this)];                // error: not inside a member function
  unsigned int sz = sizeof(*this);     // OK: in brace-or-equal-initializer

  void f() {
    int b[sizeof(*this)];              // OK

    struct Inner {
      int c[sizeof(*this)];            // error: not inside a member function of Inner
    };
  }
};
```

— *end example*]

1

A parenthesized expression is a primary expression whose type and value are identical to those of the enclosed expression. The presence of parentheses does not affect whether the expression is an lvalue. The parenthesized expression can be used in exactly the same contexts as those where the enclosed expression can be used, and with the same meaning, except as otherwise indicated.

1 An *id-expression* is a restricted form of a *primary-expression*. [*Note:* an *id-expression* can appear after `.` and `->` operators (5.1194.1). — *end note*]

2 An *identifier* is an *id-expression* provided it has been suitably declared (Clause 7). [*Note:* for *operator-function-id*s, see 13.1122; for *conversion-function-id*s, see 12.742.1; for *literal-operator-id*s, see 13.1241.1; for *template-id*s, see 14.224. A *class-name* or *decltype-specifier* prefixed by `~` denotes a destructor; see 12.807. Within the definition of a non-static member function, an *identifier* that names a non-static member is transformed to a class member access expression (9.465.1). — *end note*] The type of the expression is the type of the *identifier*. The result is the entity denoted by the identifier. The result is an lvalue if the entity is a function, variable, or data member and a prvalue otherwise.

qualified-id:
  nested-name-specifier `template`$_{opt}$ *unqualified-id*
nested-name-specifier:
  `::`
  type-name `::`
  namespace-name `::`
  decltype-specifier `::`
  nested-name-specifier identifier `::`
  nested-name-specifier `template`$_{opt}$ *simple-template-id* `::`

The type denoted by a *decltype-specifier* in a *nested-name-specifier* shall be a class or enumeration type.

1

A *nested-name-specifier* that denotes a class, optionally followed by the keyword `template` (14.224), and then followed by the name of a member of either that class (9.194) or one of its base classes (Clause 10), is a *qualified-id*; 3.1282.0.1 describes name lookup for class members that appear in *qualified-ids*. The result is the member. The type of the result is the type of the member. The result is an lvalue if the member is a static member function or a data member and a prvalue otherwise. [*Note:* a class member can be referred to using a *qualified-id* at any point in its potential scope (3.760.1). — *end note*] Where *class-name* `::~` *class-name* is used, the two *class-name*s shall refer to the same class; this notation names the destructor (12.807). The form `~` *decltype-specifier* also denotes the destructor, but it shall not be used as the *unqualified-id* in a *qualified-id*. [*Note:* a *typedef-name* that names a class is a *class-name* (9.172). — *end note*]

1 A `::`, or a *nested-name-specifier* that names a namespace (7.1142), in either case followed by the name of a member of that namespace (or the name of a member of a namespace made visible by a *using-directive*) is a *qualified-id*; 3.1363.0.1 describes name lookup for namespace members that appear in *qualified-ids*. The result is the member. The type of the result is the type of the member. The result is an lvalue if the member is a function or a variable and a prvalue otherwise.

2

A *nested-name-specifier* that denotes an enumeration (7.1001), followed by the name of an enumerator of that enumeration, is a *qualified-id* that refers to the enumerator. The result is the enumerator. The type of the result is the type of the enumeration. The result is a prvalue.

1 In a *qualified-id*, if the *unqualified-id* is a *conversion-function-id*, its *conversion-type-id* shall denote the same type in both the context in which the entire *qualified-id* occurs and in the context of the class denoted by the *nested-name-specifier*.

2

An *id-expression* that denotes a non-static data member or non-static member function of a class can only be used:

— as part of a class member access (5.1194.1) in which the object expression refers to the member's class[63] or a class derived from that class, or

— to form a pointer to member (5.1898.1), or

— if that *id-expression* denotes a non-static data member and it appears in an unevaluated operand. [*Example:*

```
struct S {
  int m;
};
int i = sizeof(S::m);          // OK
int j = sizeof(S::m + 42);     // OK
```

63) This also applies when the object expression is an implicit `(*this)` (9.465.1).

— *end example*]

5.509.1 Lambda expressions [expr.prim.lambda]

1

Lambda expressions provide a concise way to create simple function objects. [*Example:*

```
#include <algorithm>
#include <cmath>
void abssort(float* x, unsigned N) {
  std::sort(x, x + N,
    [](float a, float b) {
      return std::abs(a) < std::abs(b);
    });
}
```

— *end example*]

lambda-expression:
  lambda-introducer lambda-declarator$_{opt}$ *compound-statement*

lambda-introducer:
  `[` *lambda-capture*$_{opt}$`]`

lambda-capture:
  capture-default
  capture-list
  capture-default `,` *capture-list*

capture-default:
  `&`
  `=`

capture-list:
  capture `...`$_{opt}$
  capture-list `,` *capture* `...`$_{opt}$

capture:
  simple-capture
  init-capture

simple-capture:
  identifier
  `&` *identifier*
  `this`

init-capture:
  identifier initializer
  `&` *identifier initializer*

lambda-declarator:
  `(` *parameter-declaration-clause* `)` `mutable`$_{opt}$
    exception-specification$_{opt}$ *attribute-specifier-seq*$_{opt}$ *trailing-return-type*$_{opt}$

1

The evaluation of a *lambda-expression* results in a prvalue temporary (12.306). This temporary is called the *closure object*. A *lambda-expression* shall not appear in an unevaluated operand (Clause 5), in a *template-argument*, in an *alias-declaration*, in a typedef declaration, or in the declaration of a function or function template outside its function body and default arguments. [*Note:* The intention is to prevent lambdas from appearing in a signature. — *end note*] [*Note:* A closure object behaves like a function object (20.283). — *end note*]

1

The type of the *lambda-expression* (which is also the type of the closure object) is a unique, unnamed non-union class type — called the *closure type* — whose properties are described below. This class type is neither an aggregate (8.1817.1) nor a literal type (3.2955). The closure type is declared in the smallest block scope, class scope, or namespace scope that contains the corresponding *lambda-expression*. [*Note:* This determines the set of namespaces and classes associated with the closure type (3.1092.1). The parameter types of a *lambda-declarator* do not affect these associated namespaces and classes. — *end note*] An implementation may define the closure type differently from what is described below provided this does not alter the observable behavior of the program other than by changing:

— the size and/or alignment of the closure type,

— whether the closure type is trivially copyable (Clause 9),

— whether the closure type is a standard-layout class (Clause 9), or

— whether the closure type is a POD class (Clause 9).

An implementation shall not add members of rvalue reference type to the closure type.

1

If a *lambda-expression* does not include a *lambda-declarator*, it is as if the *lambda-declarator* were `()`. The lambda return type is `auto`, which is replaced by the *trailing-return-type* if provided and/or deduced from `return` statements as described in 7.832.0.1. [*Example:*

```
auto x1 = [](int i){ return i; };      // OK: return type is int
auto x2 = []{ return { 1, 2 }; };      // error: deducing return type from braced-init-list
int j;
auto x3 = []()->auto&& { return j; }; // OK: return type is int&
```

— *end example*]

1

The closure type for a non-generic *lambda-expression* has a public inline function call operator (13.1196.1) whose parameters and return type are described by the *lambda-expression*'s *parameter-declaration-clause* and *trailing-return-type* respectively. For a generic lambda, the closure type has a public inline function call operator member template (14.641.1) whose *template-parameter-list* consists of one invented type *template-parameter* for each occurrence of `auto` in the lambda's *parameter-declaration-clause*, in order of appearance. The invented type *template-parameter* is a parameter pack if the corresponding *parameter-declaration* declares a function parameter pack (8.360.1). The return type and function parameters of the function call operator template are derived from the *lambda-expression*'s *trailing-return-type* and *parameter-declaration-clause* by replacing each occurrence of `auto` in the *decl-specifier*s of the *parameter-declaration-clause* with the name of the corresponding invented *template-parameter*. [*Example:*

```
auto glambda = [](auto a, auto&& b) { return a < b; };
bool b = glambda(3, 3.14);                                  // OK
auto vglambda = [](auto printer) {
   return [=](auto&& ... ts) {                              // OK: ts is a function parameter pack
       printer(std::forward<decltype(ts)>(ts)...);

       return [=]() {
         printer(ts ...);
       };
   };
};
auto p = vglambda( [](auto v1, auto v2, auto v3)
                       { std::cout << v1 << v2 << v3; } );
```

```
auto q = p(1, 'a', 3.14);                    // OK: outputs 1a3.14
q();                                         // OK: outputs 1a3.14
```

— *end example*] This function call operator or operator template is declared `const` (9.465.1) if and only if the *lambda-expression*'s *parameter-declaration-clause* is not followed by `mutable`. It is neither virtual nor declared `volatile`. Any *exception-specification* specified on a *lambda-expression* applies to the corresponding function call operator or operator template. An *attribute-specifier-seq* in a *lambda-declarator* appertains to the type of the corresponding function call operator or operator template. [*Note:* Names referenced in the *lambda-declarator* are looked up in the context in which the *lambda-expression* appears. — *end note*]

1

The closure type for a non-generic *lambda-expression* with no *lambda-capture* has a public non-virtual non-explicit const conversion function to pointer to function with C++ language linkage (7.1477) having the same parameter and return types as the closure type's function call operator. The value returned by this conversion function shall be the address of a function that, when invoked, has the same effect as invoking the closure type's function call operator. For a generic lambda with no *lambda-capture*, the closure type has a public non-virtual non-explicit const conversion function template to pointer to function. The conversion function template has the same invented *template-parameter-list*, and the pointer to function has the same parameter types, as the function call operator template. The return type of the pointer to function shall behave as if it were a *decltype-specifier* denoting the return type of the corresponding function call operator template specialization. [*Note:* If the generic lambda has no *trailing-return-type* or the *trailing-return-type* contains a placeholder type, return type deduction of the corresponding function call operator template specialization has to be done. The corresponding specialization is that instantiation of the function call operator template with the same template arguments as those deduced for the conversion function template. Consider the following:

```
auto glambda = [](auto a) { return a; };
int (*fp)(int) = glambda;
```

The behavior of the conversion function of `glambda` above is like that of the following conversion function:

```
struct Closure {
  template<class T> auto operator()(T t) const { ... }
  template<class T> static auto lambda_call_operator_invoker(T a) {
    // forwards execution to operator()(a) and therefore has
    // the same return type deduced
    ...
  }
  template<class T> using fptr_t =
     decltype(lambda_call_operator_invoker(declval<T>())) (*)(T);

  template<class T> operator fptr_t<T>() const
    { return &lambda_call_operator_invoker; }
};
```

— *end note*] [*Example:*

```
void f1(int (*)(int))   { }
void f2(char (*)(int))  { }

void g(int (*)(int))    { }  // #1
void g(char (*)(char))  { }  // #2

void h(int (*)(int))    { }  // #3
```

```
void h(char (*)(int))   { }  // #4

auto glambda = [](auto a) { return a; };
f1(glambda);  // OK
f2(glambda);  // error: ID is not convertible
g(glambda);   // error: ambiguous
h(glambda);   // OK: calls #3 since it is convertible from ID
int& (*fpi)(int*) = [](auto* a) -> auto& { return *a; }; // OK
```

— *end example*] The value returned by any given specialization of this conversion function template shall be the address of a function that, when invoked, has the same effect as invoking the generic lambda's corresponding function call operator template specialization. [*Note:* This will result in the implicit instantiation of the generic lambda's body. The instantiated generic lambda's return type and parameter types shall match the return type and parameter types of the pointer to function. — *end note*] [*Example:*

```
auto GL = [](auto a) { std::cout << a; return a; };
int (*GL_int)(int) = GL;  // OK: through conversion function template
GL_int(3);                // OK: same as GL(3)
```

— *end example*]

1

The *lambda-expression*'s *compound-statement* yields the *function-body* (8.706) of the function call operator, but for purposes of name lookup (3.923), determining the type and value of `this` (9.508.1) and transforming *id-expressions* referring to non-static class members into class member access expressions using `(*this)` (9.465.1), the *compound-statement* is considered in the context of the *lambda-expression*. [*Example:*

```
struct S1 {
  int x, y;
  int operator()(int);
  void f() {
    [=]()->int {
      return operator()(this->x + y); // equivalent to S1::operator()(this->x + (*this).y)
                                      // this has type S1*
    };
  }
};
```

— *end example*] Further, a variable `__func__` is implicitly defined at the beginning of the *compound-statement* of the *lambda-expression*, with semantics as described in 8.706.1.

1

If a *lambda-capture* includes a *capture-default* that is `&`, no identifier in a *simple-capture* of that *lambda-capture* shall be preceded by `&`. If a *lambda-capture* includes a *capture-default* that is `=`, each *simple-capture* of that *lambda-capture* shall be of the form "`&` *identifier*". Ignoring appearances in *initializer*s of *init-capture*s, an identifier or `this` shall not appear more than once in a *lambda-capture*. [*Example:*

```
struct S2 { void f(int i); };
void S2::f(int i) {
  [&, i]{ };     // OK
  [&, &i]{ };    // error: i preceded by & when & is the default
  [=, this]{ }; // error: this when = is the default
  [i, i]{ };     // error: i repeated
}
```

— *end example*]

1

A *lambda-expression* whose smallest enclosing scope is a block scope (3.694.1) is a *local lambda expression*; any other *lambda-expression* shall not have a *capture-default* or *simple-capture* in its *lambda-introducer*. The *reaching scope* of a local lambda expression is the set of enclosing scopes up to and including the innermost enclosing function and its parameters. [*Note:* This reaching scope includes any intervening *lambda-expressions*. — *end note*]

1

The *identifier* in a *simple-capture* is looked up using the usual rules for unqualified name lookup (3.952.1); each such lookup shall find an entity. An entity that is designated by a *simple-capture* is said to be *explicitly captured*, and shall be `this` or a variable with automatic storage duration declared in the reaching scope of the local lambda expression.

1

An *init-capture* behaves as if it declares and explicitly captures a variable of the form "`auto` *init-capture* `;`" whose declarative region is the *lambda-expression*'s *compound-statement*, except that:

— if the capture is by copy (see below), the non-static data member declared for the capture and the variable are treated as two different ways of referring to the same object, which has the lifetime of the non-static data member, and no additional copy and destruction is performed, and

— if the capture is by reference, the variable's lifetime ends when the closure object's lifetime ends.

[*Note:* This enables an *init-capture* like "`x = std::move(x)`"; the second "`x`" must bind to a declaration in the surrounding context. — *end note*] [*Example:*

```
int x = 4;
auto y = [&r = x, x = x+1]()->int {
            r += 2;
            return x+2;
          }();  // Updates ::x to 6, and initializes y to 7.
```

— *end example*]

1

A *lambda-expression* with an associated *capture-default* that does not explicitly capture `this` or a variable with automatic storage duration (this excludes any *id-expression* that has been found to refer to an *init-capture*'s associated non-static data member), is said to *implicitly capture* the entity (i.e., `this` or a variable) if the *compound-statement*:

— odr-uses (3.91) the entity, or

— names the entity in a potentially-evaluated expression (3.91) where the enclosing full-expression depends on a generic lambda parameter declared within the reaching scope of the *lambda-expression*.

[*Example:*

```
void f(int, const int (&)[2] = {})    { }   // #1
void f(const int&, const int (&)[1])  { }   // #2
void test() {
  const int x = 17;
  auto g = [](auto a) {
    f(x);  // OK: calls #1, does not capture x
  };
```

```
  auto g2 = [=](auto a) {
    int selector[sizeof(a) == 1 ? 1 : 2]{};
    f(x, selector);  // OK: is a dependent expression, so captures x
  };
}
```

— *end example*] All such implicitly captured entities shall be declared within the reaching scope of the lambda expression. [*Note:* The implicit capture of an entity by a nested *lambda-expression* can cause its implicit capture by the containing *lambda-expression* (see below). Implicit odr-uses of `this` can result in implicit capture. — *end note*]

1

An entity is *captured* if it is captured explicitly or implicitly. An entity captured by a *lambda-expression* is odr-used (3.91) in the scope containing the *lambda-expression*. If `this` is captured by a local lambda expression, its nearest enclosing function shall be a non-static member function. If a *lambda-expression* or an instantiation of the function call operator template of a generic lambda odr-uses (3.91) `this` or a variable with automatic storage duration from its reaching scope, that entity shall be captured by the *lambda-expression*. If a *lambda-expression* captures an entity and that entity is not defined or captured in the immediately enclosing lambda expression or function, the program is ill-formed. [*Example:*

```
void f1(int i) {
  int const N = 20;
  auto m1 = [=]{
    int const M = 30;
    auto m2 = [i]{
      int x[N][M];              // OK: N and M are not odr-used
      x[0][0] = i;              // OK: i is explicitly captured by m2
                                // and implicitly captured by m1
    };
  };
  struct s1 {
    int f;
    void work(int n) {
      int m = n*n;
      int j = 40;
      auto m3 = [this,m] {
        auto m4 = [&,j] {       // error: j not captured by m3
          int x = n;            // error: n implicitly captured by m4
                                // but not captured by m3
          x += m;               // OK: m implicitly captured by m4
                                // and explicitly captured by m3
          x += i;               // error: i is outside of the reaching scope
          x += f;               // OK: this captured implicitly by m4
                                // and explicitly by m3
        };
      };
    }
  };
}
```

— *end example*]

1

A *lambda-expression* appearing in a default argument shall not implicitly or explicitly capture any entity.

[*Example:*

```
void f2() {
  int i = 1;
  void g1(int = ([i]{ return i; })());        // ill-formed
  void g2(int = ([i]{ return 0; })());        // ill-formed
  void g3(int = ([=]{ return i; })());        // ill-formed
  void g4(int = ([=]{ return 0; })());        // OK
  void g5(int = ([]{ return sizeof i; })());  // OK
}
```

— *end example*]

1

An entity is *captured by copy* if it is implicitly captured and the *capture-default* is `=` or if it is explicitly captured with a capture that is not of the form `&` *identifier* or `&` *identifier initializer*. For each entity captured by copy, an unnamed non-static data member is declared in the closure type. The declaration order of these members is unspecified. The type of such a data member is the type of the corresponding captured entity if the entity is not a reference to an object, or the referenced type otherwise. [*Note:* If the captured entity is a reference to a function, the corresponding data member is also a reference to a function. — *end note*] A member of an anonymous union shall not be captured by copy.

1

An entity is *captured by reference* if it is implicitly or explicitly captured but not captured by copy. It is unspecified whether additional unnamed non-static data members are declared in the closure type for entities captured by reference. A member of an anonymous union shall not be captured by reference.

1 If a *lambda-expression* `m2` captures an entity and that entity is captured by an immediately enclosing *lambda-expression* `m1`, then `m2`'s capture is transformed as follows:

(1.1) — if `m1` captures the entity by copy, `m2` captures the corresponding non-static data member of `m1`'s closure type;

(1.2) — if `m1` captures the entity by reference, `m2` captures the same entity captured by `m1`.

[*Example:* the nested lambda expressions and invocations below will output `123234`.

```
int a = 1, b = 1, c = 1;
auto m1 = [a, &b, &c]() mutable {
  auto m2 = [a, b, &c]() mutable {
    std::cout << a << b << c;
    a = 4; b = 4; c = 4;
  };
  a = 3; b = 3; c = 3;
  m2();
};
a = 2; b = 2; c = 2;
m1();
std::cout << a << b << c;
```

— *end example*]

2

Every *id-expression* within the *compound-statement* of a *lambda-expression* that is an odr-use (3.91) of an entity captured by copy is transformed into an access to the corresponding unnamed data member of the closure type. [*Note:* An *id-expression* that is not an odr-use refers to the original entity, never to a member of the closure type. Furthermore, such an *id-expression* does not cause the implicit capture of the entity.

— *end note*] If `this` is captured, each odr-use of `this` is transformed into an access to the corresponding unnamed data member of the closure type, cast (5.2765) to the type of `this`. [*Note:* The cast ensures that the transformed expression is a prvalue. — *end note*] [*Example:*

```
void f(const int*);
void g() {
  const int N = 10;
  [=] {
    int arr[N];              // OK: not an odr-use, refers to automatic variable
    f(&N);                   // OK: causes N to be captured; &N points to the
                             // corresponding member of the closure type
  };
}
```

— *end example*]

1

Every occurrence of `decltype((x))` where `x` is a possibly parenthesized *id-expression* that names an entity of automatic storage duration is treated as if `x` were transformed into an access to a corresponding data member of the closure type that would have been declared if `x` were an odr-use of the denoted entity. [*Example:*

```
void f3() {
  float x, &r = x;
  [=] {                      // x and r are not captured (appearance in a decltype operand is not an odr-use)
    decltype(x) y1;          // y1 has type float
    decltype((x)) y2 = y1;   // y2 has type float const& because this lambda
                             // is not mutable and x is an lvalue
    decltype(r) r1 = y1;     // r1 has type float& (transformation not considered)
    decltype((r)) r2 = y2;   // r2 has type float const&
  };
}
```

— *end example*]

1

The closure type associated with a *lambda-expression* has a deleted (8.793.1) default constructor and a deleted copy assignment operator. It has an implicitly-declared copy constructor (12.1577) and may have an implicitly-declared move constructor (12.1577). [*Note:* The copy/move constructor is implicitly defined in the same way as any other implicitly declared copy/move constructor would be implicitly defined. — *end note*]

1 The closure type associated with a *lambda-expression* has an implicitly-declared destructor (12.807).

2

When the *lambda-expression* is evaluated, the entities that are captured by copy are used to direct-initialize each corresponding non-static data member of the resulting closure object, and the non-static data members corresponding to the *init-capture*s are initialized as indicated by the corresponding *initializer* (which may be copy- or direct-initialization). (For array members, the array elements are direct-initialized in increasing subscript order.) These initializations are performed in the (unspecified) order in which the non-static data members are declared. [*Note:* This ensures that the destructions will occur in the reverse order of the constructions. — *end note*]

1

[*Note:* If an entity is implicitly or explicitly captured by reference, invoking the function call operator of the corresponding *lambda-expression* after the lifetime of the entity has ended is likely to result in undefined

behavior. — *end note*]

1

A *simple-capture* followed by an ellipsis is a pack expansion (14.703.1). An *init-capture* followed by an ellipsis is ill-formed. [*Example:*

```
template<class... Args>
void f(Args... args) {
  auto lm = [&, args...] { return g(args...); };
  lm();
}
```

— *end example*]

5.892 Postfix expressions [expr.post]

1

Postfix expressions group left-to-right.

postfix-expression:
- *primary-expression*
- *postfix-expression* `[` *expression* `]`
- *postfix-expression* `[` *braced-init-list* `]`
- *postfix-expression* `(` *expression-list*$_{opt}$ `)`
- *simple-type-specifier* `(` *expression-list*$_{opt}$ `)`
- *typename-specifier* `(` *expression-list*$_{opt}$ `)`
- *simple-type-specifier braced-init-list*
- *typename-specifier braced-init-list*
- *postfix-expression* `.` `template`$_{opt}$ *id-expression*
- *postfix-expression* `->` `template`$_{opt}$ *id-expression*
- *postfix-expression* `.` *pseudo-destructor-name*
- *postfix-expression* `->` *pseudo-destructor-name*
- *postfix-expression* `++`
- *postfix-expression* `--`
- `dynamic_cast` `<` *type-id* `>` `(` *expression* `)`
- `static_cast` `<` *type-id* `>` `(` *expression* `)`
- `reinterpret_cast` `<` *type-id* `>` `(` *expression* `)`
- `const_cast` `<` *type-id* `>` `(` *expression* `)`
- `typeid` `(` *expression* `)`
- `typeid` `(` *type-id* `)`

expression-list:
- *initializer-list*

pseudo-destructor-name:
- *nested-name-specifier*$_{opt}$ *type-name* `::` `~` *type-name*
- *nested-name-specifier* `template` *simple-template-id* `::` `~` *type-name*
- *nested-name-specifier*$_{opt}$ `~` *type-name*
- `~` *decltype-specifier*

1 [*Note:* The `>` token following the *type-id* in a `dynamic_cast`, `static_cast`, `reinterpret_cast`, or `const_cast` may be the product of replacing a `>>` token by two consecutive `>` tokens (14.224). — *end note*]

5.896.1 Subscripting [expr.sub]

1

A postfix expression followed by an expression in square brackets is a postfix expression. One of the expressions shall have the type "array of `T`" or "pointer to `T`" and the other shall have unscoped enumeration

or integral type. The result is of type "`T`." The type "`T`" shall be a completely-defined object type.[64] The expression `E1[E2]` is identical (by definition) to `*((E1)+(E2))` [*Note:* see 5.1897 and 5.2882 for details of `*` and `+` and 8.251.1 for details of arrays. — *end note*], except that in the case of an array operand, the result is an lvalue if that operand is an lvalue and an xvalue otherwise.

1

A *braced-init-list* shall not be used with the built-in subscript operator.

5.955.1 Function call [expr.call]

1

A function call is a postfix expression followed by parentheses containing a possibly empty, comma-separated list of *initializer-clause*s which constitute the arguments to the function. The postfix expression shall have function type or pointer to function type. For a call to a non-member function or to a static member function, the postfix expression shall be either an lvalue that refers to a function (in which case the function-to-pointer standard conversion (4.220) is suppressed on the postfix expression), or it shall have pointer to function type. Calling a function through an expression whose function type has a language linkage that is different from the language linkage of the function type of the called function's definition is undefined (7.1477). For a call to a non-static member function, the postfix expression shall be an implicit (9.465.1, 9.559) or explicit class member access (5.1194.1) whose *id-expression* is a function member name, or a pointer-to-member expression (5.2832) selecting a function member; the call is as a member of the class object referred to by the object expression. In the case of an implicit class member access, the implied object is the one pointed to by `this`. [*Note:* a member function call of the form `f()` is interpreted as `(*this).f()` (see 9.465.1). — *end note*] If a function or member function name is used, the name can be overloaded (Clause 13), in which case the appropriate function shall be selected according to the rules in 13.88. If the selected function is non-virtual, or if the *id-expression* in the class member access expression is a *qualified-id*, that function is called. Otherwise, its final overrider (10.113) in the dynamic type of the object expression is called; such a call is referred to as a *virtual function call*. [*Note:* the dynamic type is the type of the object referred to by the current value of the object expression. 12.1483 describes the behavior of virtual function calls when the object expression refers to an object under construction or destruction. — *end note*]

1

[*Note:* If a function or member function name is used, and name lookup (3.923) does not find a declaration of that name, the program is ill-formed. No function is implicitly declared by such a call. — *end note*]

1

If the *postfix-expression* designates a destructor (12.807), the type of the function call expression is `void`; otherwise, the type of the function call expression is the return type of the statically chosen function (i.e., ignoring the `virtual` keyword), even if the type of the function actually called is different. This return type shall be an object type, a reference type or *cv* `void`.

1

When a function is called, each parameter (8.360.1) shall be initialized (8.821, 12.1577, 12.30) with its corresponding argument. [*Note:* Such initializations are indeterminately sequenced with respect to each other (1.430) — *end note*] If the function is a non-static member function, the `this` parameter of the function (9.508.1) shall be initialized with a pointer to the object of the call, converted as if by an explicit type conversion (5.2765). [*Note:* There is no access or ambiguity checking on this conversion; the access checking and disambiguation are done as part of the (possibly implicit) class member access operator. See 10.52, 11.43, and 5.1194.1. — *end note*] When a function is called, the parameters that have object type shall have completely-defined object type. [*Note:* this still allows a parameter to be a pointer or reference to an incomplete class type. However, it prevents a passed-by-value parameter to have an incomplete class

64) This is true even if the subscript operator is used in the following common idiom: `&x[0]`.

type. — *end note*] During the initialization of a parameter, an implementation may avoid the construction of extra temporaries by combining the conversions on the associated argument and/or the construction of temporaries with the initialization of the parameter (see 12.306). The lifetime of a parameter ends when the function in which it is defined returns. The initialization and destruction of each parameter occurs within the context of the calling function. [*Example:* the access of the constructor, conversion functions or destructor is checked at the point of call in the calling function. If a constructor or destructor for a function parameter throws an exception, the search for a handler starts in the scope of the calling function; in particular, if the function called has a *function-try-block* (Clause 15) with a handler that could handle the exception, this handler is not considered. — *end example*] The value of a function call is the value returned by the called function except in a virtual function call if the return type of the final overrider is different from the return type of the statically chosen function, the value returned from the final overrider is converted to the return type of the statically chosen function.

1

[*Note:* a function can change the values of its non-const parameters, but these changes cannot affect the values of the arguments except where a parameter is of a reference type (8.97.1); if the reference is to a const-qualified type, `const_cast` is required to be used to cast away the constness in order to modify the argument's value. Where a parameter is of `const` reference type a temporary object is introduced if needed (7.519.1, 2.299, 2.453.1, 8.251.1, 12.306). In addition, it is possible to modify the values of nonconstant objects through pointer parameters. — *end note*]

1

A function can be declared to accept fewer arguments (by declaring default arguments (8.545.1)) or more arguments (by using the ellipsis, `...`, or a function parameter pack (8.360.1)) than the number of parameters in the function definition (8.706). [*Note:* this implies that, except where the ellipsis (`...`) or a function parameter pack is used, a parameter is available for each argument. — *end note*]

1

When there is no parameter for a given argument, the argument is passed in such a way that the receiving function can obtain the value of the argument by invoking `va_arg` (18.295). [*Note:* This paragraph does not apply to arguments passed to a function parameter pack. Function parameter packs are expanded during template instantiation (14.703.1), thus each such argument has a corresponding parameter when a function template specialization is actually called. — *end note*] The lvalue-to-rvalue (4.127), array-to-pointer (4.180), and function-to-pointer (4.220) standard conversions are performed on the argument expression. An argument that has (possibly cv-qualified) type `std::nullptr_t` is converted to type `void*` (4.579). After these conversions, if the argument does not have arithmetic, enumeration, pointer, pointer to member, or class type, the program is ill-formed. Passing a potentially-evaluated argument of class type (Clause 9) having a non-trivial copy constructor, a non-trivial move constructor, or a non-trivial destructor, with no corresponding parameter, is conditionally-supported with implementation-defined semantics. If the argument has integral or enumeration type that is subject to the integral promotions (4.262), or a floating point type that is subject to the floating point promotion (4.389), the value of the argument is converted to the promoted type before the call. These promotions are referred to as the *default argument promotions*.

1

[*Note:* The evaluations of the postfix expression and of the arguments are all unsequenced relative to one another. All side effects of argument evaluations are sequenced before the function is entered (see 1.430). — *end note*]

1

Recursive calls are permitted, except to the `main` function (3.1721.1).

1

A function call is an lvalue if the result type is an lvalue reference type or an rvalue reference to function type, an xvalue if the result type is an rvalue reference to object type, and a prvalue otherwise.

1

If a function call is a prvalue of object type:

— if the function call is either

— the operand of a *decltype-specifier* or

— the right operand of a comma operator that is the operand of a *decltype-specifier*,

a temporary object is not introduced for the prvalue. The type of the prvalue may be incomplete. [*Note:* as a result, storage is not allocated for the prvalue and it is not destroyed; thus, a class type is not instantiated as a result of being the type of a function call in this context. This is true regardless of whether the expression uses function call notation or operator notation (13.264.0.1). — *end note*] [*Note:* unlike the rule for a *decltype-specifier* that considers whether an *id-expression* is parenthesized (7.678.0.1), parentheses have no special meaning in this context. — *end note*]

— otherwise, the type of the prvalue shall be complete.

5.1108.1 Explicit type conversion (functional notation) [expr.type.conv]

1

A *simple-type-specifier* (7.678.0.1) or *typename-specifier* (14.1061) followed by a parenthesized *expression-list* constructs a value of the specified type given the expression list. If the expression list is a single expression, the type conversion expression is equivalent (in definedness, and if defined in meaning) to the corresponding cast expression (5.2765). If the type specified is a class type, the class type shall be complete. If the expression list specifies more than a single value, the type shall be a class with a suitably declared constructor (8.821, 12.30), and the expression `T(x1, x2, ...)` is equivalent in effect to the declaration `T t(x1, x2, ...);` for some invented temporary variable `t`, with the result being the value of `t` as a prvalue.

1

The expression `T()`, where `T` is a *simple-type-specifier* or *typename-specifier* for a non-array complete object type or the (possibly cv-qualified) `void` type, creates a prvalue of the specified type, whose value is that produced by value-initializing (8.821) an object of type `T`; no initialization is done for the `void()` case. [*Note:* if `T` is a non-class type that is cv-qualified, the *cv-qualifier*s are discarded when determining the type of the resulting prvalue (Clause 5). — *end note*]

1

Similarly, a *simple-type-specifier* or *typename-specifier* followed by a *braced-init-list* creates a temporary object of the specified type direct-list-initialized (8.2435.1) with the specified *braced-init-list*, and its value is that temporary object as a prvalue.

5.1181.1 Pseudo destructor call [expr.pseudo]

1

The use of a *pseudo-destructor-name* after a dot `.` or arrow `->` operator represents the destructor for the non-class type denoted by *type-name* or *decltype-specifier*. The result shall only be used as the operand for the function call operator `()`, and the result of such a call has type `void`. The only effect is the evaluation of the *postfix-expression* before the dot or arrow.

1

The left-hand side of the dot operator shall be of scalar type. The left-hand side of the arrow operator shall be of pointer to scalar type. This scalar type is the object type. The *cv*-unqualified versions of the object

type and of the type designated by the *pseudo-destructor-name* shall be the same type. Furthermore, the two *type-name*s in a *pseudo-destructor-name* of the form

nested-name-specifier$_{opt}$ *type-name* `::` `~` *type-name*

shall designate the same scalar type.

5.1194.1 Class member access [expr.ref]

1

A postfix expression followed by a dot `.` or an arrow `->`, optionally followed by the keyword `template` (14.224), and then followed by an *id-expression*, is a postfix expression. The postfix expression before the dot or arrow is evaluated;[65] the result of that evaluation, together with the *id-expression*, determines the result of the entire postfix expression.

1

For the first option (dot) the first expression shall have complete class type. For the second option (arrow) the first expression shall have pointer to complete class type. The expression `E1->E2` is converted to the equivalent form `(*(E1)).E2`; the remainder of 5.1194.1 will address only the first option (dot).[66] In either case, the *id-expression* shall name a member of the class or of one of its base classes. [*Note:* because the name of a class is inserted in its class scope (Clause 9), the name of a class is also considered a nested member of that class. — *end note*] [*Note:* 3.1423.1 describes how names are looked up after the `.` and `->` operators. — *end note*]

1

Abbreviating *postfix-expression.id-expression* as `E1.E2`, `E1` is called the *object expression*. The type and value category of `E1.E2` are determined as follows. In the remainder of 5.1194.1, *cq* represents either `const` or the absence of `const` and *vq* represents either `volatile` or the absence of `volatile`. *cv* represents an arbitrary set of cv-qualifiers, as defined in 3.3640.1.

1

If `E2` is declared to have type "reference to `T`," then `E1.E2` is an lvalue; the type of `E1.E2` is `T`. Otherwise, one of the following rules applies.

— If `E2` is a static data member and the type of `E2` is `T`, then `E1.E2` is an lvalue; the expression designates the named member of the class. The type of `E1.E2` is `T`.

— If `E2` is a non-static data member and the type of `E1` is "*cq1 vq1* `X`", and the type of `E2` is "*cq2 vq2* `T`", the expression designates the named member of the object designated by the first expression. If `E1` is an lvalue, then `E1.E2` is an lvalue; otherwise `E1.E2` is an xvalue. Let the notation *vq12* stand for the "union" of *vq1* and *vq2*; that is, if *vq1* or *vq2* is `volatile`, then *vq12* is `volatile`. Similarly, let the notation *cq12* stand for the "union" of *cq1* and *cq2*; that is, if *cq1* or *cq2* is `const`, then *cq12* is `const`. If `E2` is declared to be a `mutable` member, then the type of `E1.E2` is "*vq12* `T`". If `E2` is not declared to be a `mutable` member, then the type of `E1.E2` is "*cq12 vq12* `T`".

— If `E2` is a (possibly overloaded) member function, function overload resolution (13.88) is used to determine whether `E1.E2` refers to a static or a non-static member function.

  — If it refers to a static member function and the type of `E2` is "function of parameter-type-list returning `T`", then `E1.E2` is an lvalue; the expression designates the static member function. The type of `E1.E2` is the same type as that of `E2`, namely "function of parameter-type-list returning `T`".

65) If the class member access expression is evaluated, the subexpression evaluation happens even if the result is unnecessary to determine the value of the entire postfix expression, for example if the *id-expression* denotes a static member.

66) Note that `(*(E1))` is an lvalue.

— Otherwise, if `E1.E2` refers to a non-static member function and the type of `E2` is "function of parameter-type-list *cv ref-qualifier*$_{opt}$ returning `T`", then `E1.E2` is a prvalue. The expression designates a non-static member function. The expression can be used only as the left-hand operand of a member function call (9.401). [*Note:* Any redundant set of parentheses surrounding the expression is ignored (5.398). — *end note*] The type of `E1.E2` is "function of parameter-type-list *cv* returning `T`".

— If `E2` is a nested type, the expression `E1.E2` is ill-formed.

— If `E2` is a member enumerator and the type of `E2` is `T`, the expression `E1.E2` is a prvalue. The type of `E1.E2` is `T`.

1

If `E2` is a non-static data member or a non-static member function, the program is ill-formed if the class of which `E2` is directly a member is an ambiguous base (10.52) of the naming class (11.43) of `E2`. [*Note:* The program is also ill-formed if the naming class is an ambiguous base of the class type of the object expression; see 11.43. — *end note*]

5.1264.1 Increment and decrement [expr.post.incr]

1

The value of a postfix `++` expression is the value of its operand. [*Note:* the value obtained is a copy of the original value — *end note*] The operand shall be a modifiable lvalue. The type of the operand shall be an arithmetic type or a pointer to a complete object type. The value of the operand object is modified by adding `1` to it, unless the object is of type `bool`, in which case it is set to `true`. [*Note:* this use is deprecated, see Annex D. — *end note*] The value computation of the `++` expression is sequenced before the modification of the operand object. With respect to an indeterminately-sequenced function call, the operation of postfix `++` is a single evaluation. [*Note:* Therefore, a function call shall not intervene between the lvalue-to-rvalue conversion and the side effect associated with any single postfix ++ operator. — *end note*] The result is a prvalue. The type of the result is the cv-unqualified version of the type of the operand. See also 5.2882 and 5.3483.

1

The operand of postfix `--` is decremented analogously to the postfix `++` operator, except that the operand shall not be of type `bool`. [*Note:* For prefix increment and decrement, see 5.2054.1. — *end note*]

5.1295.1 Dynamic cast [expr.dynamic.cast]

1

The result of the expression `dynamic_cast<T>(v)` is the result of converting the expression `v` to type `T`. `T` shall be a pointer or reference to a complete class type, or "pointer to *cv* `void`." The `dynamic_cast` operator shall not cast away constness (5.1871.1).

1

If `T` is a pointer type, `v` shall be a prvalue of a pointer to complete class type, and the result is a prvalue of type `T`. If `T` is an lvalue reference type, `v` shall be an lvalue of a complete class type, and the result is an lvalue of the type referred to by `T`. If `T` is an rvalue reference type, `v` shall be an expression having a complete class type, and the result is an xvalue of the type referred to by `T`.

1

If the type of `v` is the same as `T`, or it is the same as `T` except that the class object type in `T` is more cv-qualified than the class object type in `v`, the result is `v` (converted if necessary).

1

If the value of `v` is a null pointer value in the pointer case, the result is the null pointer value of type `T`.

1

If `T` is "pointer to *cv1* `B`" and `v` has type "pointer to *cv2* `D`" such that `B` is a base class of `D`, the result is a pointer to the unique `B` subobject of the `D` object pointed to by `v`. Similarly, if `T` is "reference to *cv1* `B`" and `v` has type *cv2* `D` such that `B` is a base class of `D`, the result is the unique `B` subobject of the `D` object referred to by `v`. [67] The result is an lvalue if `T` is an lvalue reference, or an xvalue if `T` is an rvalue reference. In both the pointer and reference cases, the program is ill-formed if *cv2* has greater cv-qualification than *cv1* or if `B` is an inaccessible or ambiguous base class of `D`. [*Example:*

```
struct B { };
struct D : B { };
void foo(D* dp) {
  B*  bp = dynamic_cast<B*>(dp);     // equivalent to B* bp = dp;
}
```

— *end example*]

1

Otherwise, `v` shall be a pointer to or a glvalue of a polymorphic type (10.113).

1

If `T` is "pointer to *cv* `void`," then the result is a pointer to the most derived object pointed to by `v`. Otherwise, a run-time check is applied to see if the object pointed or referred to by `v` can be converted to the type pointed or referred to by `T`.

1

If `C` is the class type to which `T` points or refers, the run-time check logically executes as follows:

— If, in the most derived object pointed (referred) to by `v`, `v` points (refers) to a `public` base class subobject of a `C` object, and if only one object of type `C` is derived from the subobject pointed (referred) to by `v` the result points (refers) to that `C` object.

— Otherwise, if `v` points (refers) to a `public` base class subobject of the most derived object, and the type of the most derived object has a base class, of type `C`, that is unambiguous and `public`, the result points (refers) to the `C` subobject of the most derived object.

— Otherwise, the run-time check *fails*.

1

The value of a failed cast to pointer type is the null pointer value of the required result type. A failed cast to reference type throws an exception (15.7) of a type that would match a handler (15.146) of type `std::bad_cast` (18.240.1).

[*Example:*

```
class A { virtual void f(); };
class B { virtual void g(); };
class D : public virtual A, private B { };
void g() {
  D   d;
  B*  bp = (B*)&d;                  // cast needed to break protection
  A*  ap = &d;                      // public derivation, no cast needed
  D&  dr = dynamic_cast<D&>(*bp);   // fails
```

67) The most derived object (1.319) pointed or referred to by `v` can contain other `B` objects as base classes, but these are ignored.

```
  ap = dynamic_cast<A*>(bp);        // fails
  bp = dynamic_cast<B*>(ap);        // fails
  ap = dynamic_cast<A*>(&d);        // succeeds
  bp = dynamic_cast<B*>(&d);        // ill-formed (not a run-time check)
}

class E : public D, public B { };
class F : public E, public D { };
void h() {
  F   f;
  A*  ap  = &f;                     // succeeds: finds unique A
  D*  dp  = dynamic_cast<D*>(ap);   // fails: yields 0
                                    // f has two D subobjects
  E*  ep  = (E*)ap;                 // ill-formed: cast from virtual base
  E*  ep1 = dynamic_cast<E*>(ap);   // succeeds
}
```

— *end example*] [*Note:* 12.1483 describes the behavior of a `dynamic_cast` applied to an object under construction or destruction. — *end note*]

5.1393.1 Type identification [expr.typeid]

1

The result of a `typeid` expression is an lvalue of static type `const std::type_info` (18.227.1) and dynamic type `const std::type_info` or `const` *name* where *name* is an implementation-defined class publicly derived from `std::type_info` which preserves the behavior described in 18.227.1.[68] The lifetime of the object referred to by the lvalue extends to the end of the program. Whether or not the destructor is called for the `std::type_info` object at the end of the program is unspecified.

1

When `typeid` is applied to a glvalue expression whose type is a polymorphic class type (10.113), the result refers to a `std::type_info` object representing the type of the most derived object (1.319) (that is, the dynamic type) to which the glvalue refers. If the glvalue expression is obtained by applying the unary `*` operator to a pointer[69] and the pointer is a null pointer value (4.579), the `typeid` expression throws an exception (15.7) of a type that would match a handler of type `std::bad_typeid` exception (18.240.2).

1

When `typeid` is applied to an expression other than a glvalue of a polymorphic class type, the result refers to a `std::type_info` object representing the static type of the expression. Lvalue-to-rvalue (4.127), array-to-pointer (4.180), and function-to-pointer (4.220) conversions are not applied to the expression. If the type of the expression is a class type, the class shall be completely-defined. The expression is an unevaluated operand (Clause 5).

1

When `typeid` is applied to a *type-id*, the result refers to a `std::type_info` object representing the type of the *type-id*. If the type of the *type-id* is a reference to a possibly *cv*-qualified type, the result of the `typeid` expression refers to a `std::type_info` object representing the *cv*-unqualified referenced type. If the type of the *type-id* is a class type or a reference to a class type, the class shall be completely-defined.

1

If the type of the expression or *type-id* is a cv-qualified type, the result of the `typeid` expression refers to a `std::type_info` object representing the cv-unqualified type. [*Example:*

68) The recommended name for such a class is `extended_type_info`.

69) If `p` is an expression of pointer type, then `*p`, `(*p)`, `*(p)`, `((*p))`, `*((p))`, and so on all meet this requirement.

```
class D { /* ...  */ };
D d1;
const D d2;

typeid(d1) == typeid(d2);       // yields true
typeid(D)  == typeid(const D);  // yields true
typeid(D)  == typeid(d2);       // yields true
typeid(D)  == typeid(const D&); // yields true
```

— *end example*]

1

If the header `<typeinfo>` (18.227.1) is not included prior to a use of `typeid`, the program is ill-formed.

1 [*Note:* 12.1483 describes the behavior of `typeid` applied to an object under construction or destruction. — *end note*]

5.1443.1 Static cast [expr.static.cast]

1

The result of the expression `static_cast<T>(v)` is the result of converting the expression `v` to type `T`. If `T` is an lvalue reference type or an rvalue reference to function type, the result is an lvalue; if `T` is an rvalue reference to object type, the result is an xvalue; otherwise, the result is a prvalue. The `static_cast` operator shall not cast away constness (5.1871.1).

1

An lvalue of type "*cv1* `B`," where `B` is a class type, can be cast to type "reference to *cv2* `D`," where `D` is a class derived (Clause 10) from `B`, if a valid standard conversion from "pointer to `D`" to "pointer to `B`" exists (4.579), *cv2* is the same cv-qualification as, or greater cv-qualification than, *cv1*, and `B` is neither a virtual base class of `D` nor a base class of a virtual base class of `D`. The result has type "*cv2* `D`." An xvalue of type "*cv1* `B`" may be cast to type "rvalue reference to *cv2* `D`" with the same constraints as for an lvalue of type "*cv1* `B`." If the object of type "*cv1* `B`" is actually a subobject of an object of type `D`, the result refers to the enclosing object of type `D`. Otherwise, the behavior is undefined. [*Example:*

```
struct B { };
struct D : public B { };
D d;
B &br = d;

static_cast<D&>(br);            // produces lvalue to the original d object
```

— *end example*]

1

A glvalue, class prvalue, or array prvalue of type "*cv1* `T1`" can be cast to type "rvalue reference to *cv2* `T2`" if "*cv2* `T2`" is reference-compatible with "*cv1* `T1`" (8.2156.1). If the value is not a bit-field, the result refers to the object or the specified base class subobject thereof; otherwise, the lvalue-to-rvalue conversion (4.127) is applied to the bit-field and the resulting prvalue is used as the *expression* of the `static_cast` for the remainder of this section. If `T2` is an inaccessible (Clause 11) or ambiguous (10.52) base class of `T1`, a program that necessitates such a cast is ill-formed.

1

An expression `e` can be explicitly converted to a type `T` using a `static_cast` of the form `static_cast<T>(e)` if the declaration `T t(e);` is well-formed, for some invented temporary variable `t` (8.821). The effect of such an explicit conversion is the same as performing the declaration and initialization and then using the

temporary variable as the result of the conversion. The expression `e` is used as a glvalue if and only if the initialization uses it as a glvalue.

1

Otherwise, the `static_cast` shall perform one of the conversions listed below. No other conversion shall be performed explicitly using a `static_cast`.

1

Any expression can be explicitly converted to type *cv* `void`, in which case it becomes a discarded-value expression (Clause 5). [*Note:* however, if the value is in a temporary object (12.306), the destructor for that object is not executed until the usual time, and the value of the object is preserved for the purpose of executing the destructor. — *end note*]

1

The inverse of any standard conversion sequence (Clause 4) not containing an lvalue-to-rvalue (4.127), array-to-pointer (4.180), function-to-pointer (4.220), null pointer (4.579), null member pointer (4.710), or boolean (4.732) conversion, can be performed explicitly using `static_cast`. A program is ill-formed if it uses `static_cast` to perform the inverse of an ill-formed standard conversion sequence. [*Example:*

```
struct B { };
struct D : private B { };
void f() {
  static_cast<D*>((B*)0);                // Error: B is a private base of D.
  static_cast<int B::*>((int D::*)0);    // Error: B is a private base of D.
}
```

— *end example*]

1

The lvalue-to-rvalue (4.127), array-to-pointer (4.180), and function-to-pointer (4.220) conversions are applied to the operand. Such a `static_cast` is subject to the restriction that the explicit conversion does not cast away constness (5.1871.1), and the following additional rules for specific cases:

1

A value of a scoped enumeration type (7.1001) can be explicitly converted to an integral type. When that type is *cv* `bool`, the resulting value is `false` if the original value is zero and `true` for all other values. For the remaining integral types, the value is unchanged if the original value can be represented by the specified type. Otherwise, the resulting value is unspecified. A value of a scoped enumeration type can also be explicitly converted to a floating-point type; the result is the same as that of converting from the original value to the floating-point type.

1

A value of integral or enumeration type can be explicitly converted to an enumeration type. The value is unchanged if the original value is within the range of the enumeration values (7.1001). Otherwise, the resulting value is unspecified (and might not be in that range). A value of floating-point type can also be explicitly converted to an enumeration type. The resulting value is the same as converting the original value to the underlying type of the enumeration (4.532), and subsequently to the enumeration type.

1

A prvalue of type "pointer to *cv1* `B`," where `B` is a class type, can be converted to a prvalue of type "pointer to *cv2* `D`," where `D` is a class derived (Clause 10) from `B`, if a valid standard conversion from "pointer to `D`" to "pointer to `B`" exists (4.579), *cv2* is the same cv-qualification as, or greater cv-qualification than, *cv1*, and `B` is neither a virtual base class of `D` nor a base class of a virtual base class of `D`. The null pointer value (4.579) is converted to the null pointer value of the destination type. If the prvalue of type "pointer to *cv1* `B`" points

to a B that is actually a subobject of an object of type D, the resulting pointer points to the enclosing object of type D. Otherwise, the behavior is undefined.

1

A prvalue of type "pointer to member of D of type *cv1* T" can be converted to a prvalue of type "pointer to member of B" of type *cv2* T, where B is a base class (Clause 10) of D, if a valid standard conversion from "pointer to member of B of type T" to "pointer to member of D of type T" exists (4.710), and *cv2* is the same cv-qualification as, or greater cv-qualification than, *cv1*.[70] The null member pointer value (4.710) is converted to the null member pointer value of the destination type. If class B contains the original member, or is a base or derived class of the class containing the original member, the resulting pointer to member points to the original member. Otherwise, the behavior is undefined. [*Note:* although class B need not contain the original member, the dynamic type of the object with which indirection through the pointer to member is performed must contain the original member; see 5.2832. — *end note*]

1

A prvalue of type "pointer to *cv1* void" can be converted to a prvalue of type "pointer to *cv2* T," where T is an object type and *cv2* is the same cv-qualification as, or greater cv-qualification than, *cv1*. The null pointer value is converted to the null pointer value of the destination type. If the original pointer value represents the address A of a byte in memory and A satisfies the alignment requirement of T, then the resulting pointer value represents the same address as the original pointer value, that is, A. The result of any other such pointer conversion is unspecified. A value of type pointer to object converted to "pointer to *cv* void" and back, possibly with different cv-qualification, shall have its original value. [*Example:*

```
T* p1 = new T;
const T* p2 = static_cast<const T*>(static_cast<void*>(p1));
bool b = p1 == p2;  // b will have the value true.
```

— *end example*]

5.1644.1 Reinterpret cast [expr.reinterpret.cast]

1

The result of the expression `reinterpret_cast<T>(v)` is the result of converting the expression v to type T. If T is an lvalue reference type or an rvalue reference to function type, the result is an lvalue; if T is an rvalue reference to object type, the result is an xvalue; otherwise, the result is a prvalue and the lvalue-to-rvalue (4.127), array-to-pointer (4.180), and function-to-pointer (4.220) standard conversions are performed on the expression v. Conversions that can be performed explicitly using `reinterpret_cast` are listed below. No other conversion can be performed explicitly using `reinterpret_cast`.

1

The `reinterpret_cast` operator shall not cast away constness (5.1871.1). An expression of integral, enumeration, pointer, or pointer-to-member type can be explicitly converted to its own type; such a cast yields the value of its operand.

1

[*Note:* The mapping performed by `reinterpret_cast` might, or might not, produce a representation different from the original value. — *end note*]

1

A pointer can be explicitly converted to any integral type large enough to hold it. The mapping function is implementation-defined. [*Note:* It is intended to be unsurprising to those who know the addressing structure of the underlying machine. — *end note*] A value of type `std::nullptr_t` can be converted to an integral

70) Function types (including those used in pointer to member function types) are never cv-qualified; see 8.360.1.

type; the conversion has the same meaning and validity as a conversion of `(void*)0` to the integral type. [*Note:* A `reinterpret_cast` cannot be used to convert a value of any type to the type `std::nullptr_t`. — *end note*]

1

A value of integral type or enumeration type can be explicitly converted to a pointer. A pointer converted to an integer of sufficient size (if any such exists on the implementation) and back to the same pointer type will have its original value; mappings between pointers and integers are otherwise implementation-defined. [*Note:* Except as described in 3.2532.0.1, the result of such a conversion will not be a safely-derived pointer value. — *end note*]

1

A function pointer can be explicitly converted to a function pointer of a different type. The effect of calling a function through a pointer to a function type (8.360.1) that is not the same as the type used in the definition of the function is undefined. Except that converting a prvalue of type "pointer to `T1`" to the type "pointer to `T2`" (where `T1` and `T2` are function types) and back to its original type yields the original pointer value, the result of such a pointer conversion is unspecified. [*Note:* see also 4.579 for more details of pointer conversions. — *end note*]

1

An object pointer can be explicitly converted to an object pointer of a different type.[71] When a prvalue `v` of object pointer type is converted to the object pointer type "pointer to *cv* `T`", the result is `static_cast<`*cv* `T*>(static_cast<`*cv* `void*>(v))`. Converting a prvalue of type "pointer to `T1`" to the type "pointer to `T2`" (where `T1` and `T2` are object types and where the alignment requirements of `T2` are no stricter than those of `T1`) and back to its original type yields the original pointer value.

1

Converting a function pointer to an object pointer type or vice versa is conditionally-supported. The meaning of such a conversion is implementation-defined, except that if an implementation supports conversions in both directions, converting a prvalue of one type to the other type and back, possibly with different cv-qualification, shall yield the original pointer value.

1

The null pointer value (4.579) is converted to the null pointer value of the destination type. [*Note:* A null pointer constant of type `std::nullptr_t` cannot be converted to a pointer type, and a null pointer constant of integral type is not necessarily converted to a null pointer value. — *end note*]

1

A prvalue of type "pointer to member of `X` of type `T1`" can be explicitly converted to a prvalue of a different type "pointer to member of `Y` of type `T2`" if `T1` and `T2` are both function types or both object types.[72] The null member pointer value (4.710) is converted to the null member pointer value of the destination type. The result of this conversion is unspecified, except in the following cases:

— converting a prvalue of type "pointer to member function" to a different pointer to member function type and back to its original type yields the original pointer to member value.

— converting a prvalue of type "pointer to data member of `X` of type `T1`" to the type "pointer to data member of `Y` of type `T2`" (where the alignment requirements of `T2` are no stricter than those of `T1`) and back to its original type yields the original pointer to member value.

71) The types may have different *cv*-qualifiers, subject to the overall restriction that a `reinterpret_cast` cannot cast away constness.

72) `T1` and `T2` may have different *cv*-qualifiers, subject to the overall restriction that a `reinterpret_cast` cannot cast away constness.

1

A glvalue expression of type `T1` can be cast to the type "reference to `T2`" if an expression of type "pointer to `T1`" can be explicitly converted to the type "pointer to `T2`" using a `reinterpret_cast`. The result refers to the same object as the source glvalue, but with the specified type. [*Note:* That is, for lvalues, a reference cast `reinterpret_cast<T&>(x)` has the same effect as the conversion `*reinterpret_cast<T*>(&x)` with the built-in `&` and `*` operators (and similarly for `reinterpret_cast<T&&>(x)`). — *end note*] No temporary is created, no copy is made, and constructors (12.30) or conversion functions (12.659) are not called.[73]

5.1871.1 Const cast [expr.const.cast]

1

The result of the expression `const_cast<T>(v)` is of type `T`. If `T` is an lvalue reference to object type, the result is an lvalue; if `T` is an rvalue reference to object type, the result is an xvalue; otherwise, the result is a prvalue and the lvalue-to-rvalue (4.127), array-to-pointer (4.180), and function-to-pointer (4.220) standard conversions are performed on the expression `v`. Conversions that can be performed explicitly using `const_cast` are listed below. No other conversion shall be performed explicitly using `const_cast`.

1 [*Note:* Subject to the restrictions in this section, an expression may be cast to its own type using a `const_cast` operator. — *end note*]

2

For two pointer types `T1` and `T2` where

T1 is $cv_{1,0}$ pointer to $cv_{1,1}$ pointer to $\cdots$ $cv_{1,n-1}$ pointer to $cv_{1,n}$ T

and

T2 is $cv_{2,0}$ pointer to $cv_{2,1}$ pointer to $\cdots$ $cv_{2,n-1}$ pointer to $cv_{2,n}$ T

where `T` is any object type or the `void` type and where $cv_{1,k}$ and $cv_{2,k}$ may be different cv-qualifications, a prvalue of type `T1` may be explicitly converted to the type `T2` using a `const_cast`. The result of a pointer `const_cast` refers to the original object.

1 For two object types `T1` and `T2`, if a pointer to `T1` can be explicitly converted to the type "pointer to `T2`" using a `const_cast`, then the following conversions can also be made:

(1.1) — an lvalue of type `T1` can be explicitly converted to an lvalue of type `T2` using the cast `const_cast<T2&>`;

(1.2) — a glvalue of type `T1` can be explicitly converted to an xvalue of type `T2` using the cast `const_cast<T2&&>`; and

(1.3) — if `T1` is a class type, a prvalue of type `T1` can be explicitly converted to an xvalue of type `T2` using the cast `const_cast<T2&&>`.

The result of a reference `const_cast` refers to the original object.

2 For a `const_cast` involving pointers to data members, multi-level pointers to data members and multi-level mixed pointers and pointers to data members (4.246), the rules for `const_cast` are the same as those used for pointers; the "member" aspect of a pointer to member is ignored when determining where the cv-qualifiers are added or removed by the `const_cast`. The result of a pointer to data member `const_cast` refers to the same member as the original (uncast) pointer to data member.

3 A null pointer value (4.579) is converted to the null pointer value of the destination type. The null member pointer value (4.710) is converted to the null member pointer value of the destination type.

4

73) This is sometimes referred to as a *type pun*.

[*Note:* Depending on the type of the object, a write operation through the pointer, lvalue or pointer to data member resulting from a `const_cast` that casts away a const-qualifier[74] may produce undefined behavior (7.567.0.1). — *end note*]

1

The following rules define the process known as *casting away constness*. In these rules `T`n and `X`n represent types. For two pointer types:

`X1` is `T1`$cv_{1,1}$ `*` $\cdots$ $cv_{1,N}$ `*` where `T1` is not a pointer type

`X2` is `T2`$cv_{2,1}$ `*` $\cdots$ $cv_{2,M}$ `*` where `T2` is not a pointer type

K is $\min(N, M)$

casting from `X1` to `X2` casts away constness if, for a non-pointer type `T` there does not exist an implicit conversion (Clause 4) from:

`T`$cv_{1,(N-K+1)}$ `*` $cv_{1,(N-K+2)}$ `*` $\cdots$ $cv_{1,N}$ `*`

to

`T`$cv_{2,(M-K+1)}$ `*` $cv_{2,(M-K+2)}$ `*` $\cdots$ $cv_{2,M}$ `*`

1 Casting from an lvalue of type `T1` to an lvalue of type `T2` using an lvalue reference cast or casting from an expression of type `T1` to an xvalue of type `T2` using an rvalue reference cast casts away constness if a cast from a prvalue of type "pointer to `T1`" to the type "pointer to `T2`" casts away constness.

2 Casting from a prvalue of type "pointer to data member of `X` of type `T1`" to the type "pointer to data member of `Y` of type `T2`" casts away constness if a cast from a prvalue of type "pointer to `T1`" to the type "pointer to `T2`" casts away constness.

3 For multi-level pointer to members and multi-level mixed pointers and pointer to members (4.246), the "member" aspect of a pointer to member level is ignored when determining if a `const` cv-qualifier has been cast away.

4

[*Note:* some conversions which involve only changes in cv-qualification cannot be done using `const_cast`. For instance, conversions between pointers to functions are not covered because such conversions lead to values whose use causes undefined behavior. For the same reasons, conversions between pointers to member functions, and in particular, the conversion from a pointer to a const member function to a pointer to a non-const member function, are not covered. — *end note*]

5.1897 Unary expressions [expr.unary]

1

Expressions with unary operators group right-to-left.

unary-expression:
- *postfix-expression*
- `++` *cast-expression*
- `--` *cast-expression*
- *unary-operator cast-expression*
- `sizeof` *unary-expression*
- `sizeof (` *type-id* `)`
- `sizeof ... (` *identifier* `)`
- `alignof (` *type-id* `)`
- *noexcept-expression*
- *new-expression*
- *delete-expression*

74) `const_cast` is not limited to conversions that cast away a const-qualifier.

unary-operator: one of
`* & + - ! ~`

5.1898.1 Unary operators [expr.unary.op]

1

The unary `*` operator performs *indirection*: the expression to which it is applied shall be a pointer to an object type, or a pointer to a function type and the result is an lvalue referring to the object or function to which the expression points. If the type of the expression is "pointer to `T`," the type of the result is "`T`." [*Note:* indirection through a pointer to an incomplete type (other than *cv* `void`) is valid. The lvalue thus obtained can be used in limited ways (to initialize a reference, for example); this lvalue must not be converted to a prvalue, see 4.127. — *end note*]

1

The result of each of the following unary operators is a prvalue.

1

The result of the unary `&` operator is a pointer to its operand. The operand shall be an lvalue or a *qualified-id*. If the operand is a *qualified-id* naming a non-static member `m` of some class `C` with type `T`, the result has type "pointer to member of class `C` of type `T`" and is a prvalue designating `C::m`. Otherwise, if the type of the expression is `T`, the result has type "pointer to `T`" and is a prvalue that is the address of the designated object (1.277) or a pointer to the designated function. [*Note:* In particular, the address of an object of type "*cv* `T`" is "pointer to *cv* `T`", with the same cv-qualification. — *end note*] [*Example:*

```
struct A { int i; };
struct B : A { };
... &B::i ...        // has type int A::*
```

— *end example*] [*Note:* a pointer to member formed from a `mutable` non-static data member (7.49.1) does not reflect the `mutable` specifier associated with the non-static data member. — *end note*]

1

A pointer to member is only formed when an explicit `&` is used and its operand is a *qualified-id* not enclosed in parentheses. [*Note:* that is, the expression `&(qualified-id)`, where the *qualified-id* is enclosed in parentheses, does not form an expression of type "pointer to member." Neither does `qualified-id`, because there is no implicit conversion from a *qualified-id* for a non-static member function to the type "pointer to member function" as there is from an lvalue of function type to the type "pointer to function" (4.220). Nor is `&unqualified-id` a pointer to member, even within the scope of the *unqualified-id*'s class. — *end note*]

1

If `&` is applied to an lvalue of incomplete class type and the complete type declares `operator&()`, it is unspecified whether the operator has the built-in meaning or the operator function is called. The operand of `&` shall not be a bit-field.

1

The address of an overloaded function (Clause 13) can be taken only in a context that uniquely determines which version of the overloaded function is referred to (see 13.1084). [*Note:* since the context might determine whether the operand is a static or non-static member function, the context can also affect whether the expression has type "pointer to function" or "pointer to member function." — *end note*]

1

The operand of the unary `+` operator shall have arithmetic, unscoped enumeration, or pointer type and the result is the value of the argument. Integral promotion is performed on integral or enumeration operands. The type of the result is the type of the promoted operand.

1

The operand of the unary `-` operator shall have arithmetic or unscoped enumeration type and the result is the negation of its operand. Integral promotion is performed on integral or enumeration operands. The negative of an unsigned quantity is computed by subtracting its value from 2^n, where n is the number of bits in the promoted operand. The type of the result is the type of the promoted operand.

1

The operand of the logical negation operator `!` is contextually converted to `bool` (Clause 4); its value is `true` if the converted operand is `false` and `false` otherwise. The type of the result is `bool`.

1

The operand of `~` shall have integral or unscoped enumeration type; the result is the one's complement of its operand. Integral promotions are performed. The type of the result is the type of the promoted operand. There is an ambiguity in the *unary-expression* `~X()`, where `X` is a *class-name* or *decltype-specifier*. The ambiguity is resolved in favor of treating `~` as a unary complement rather than treating `~X` as referring to a destructor.

5.2054.1 Increment and decrement [expr.pre.incr]

1

The operand of prefix `++` is modified by adding `1`, or set to `true` if it is `bool` (this use is deprecated). The operand shall be a modifiable lvalue. The type of the operand shall be an arithmetic type or a pointer to a completely-defined object type. The result is the updated operand; it is an lvalue, and it is a bit-field if the operand is a bit-field. If `x` is not of type `bool`, the expression `++x` is equivalent to `x+=1` [*Note:* See the discussions of addition (5.2882) and assignment operators (5.3483) for information on conversions. — *end note*]

1

The operand of prefix `--` is modified by subtracting `1`. The operand shall not be of type `bool`. The requirements on the operand of prefix `--` and the properties of its result are otherwise the same as those of prefix `++`. [*Note:* For postfix increment and decrement, see 5.1264.1. — *end note*]

5.2075.1 Sizeof [expr.sizeof]

1

The `sizeof` operator yields the number of bytes in the object representation of its operand. The operand is either an expression, which is an unevaluated operand (Clause 5), or a parenthesized *type-id*. The `sizeof` operator shall not be applied to an expression that has function or incomplete type, to an enumeration type whose underlying type is not fixed before all its enumerators have been declared, to the parenthesized name of such types, or to a glvalue that designates a bit-field. `sizeof(char)`, `sizeof(signed char)` and `sizeof(unsigned char)` are `1`. The result of `sizeof` applied to any other fundamental type (3.3151.1) is implementation-defined. [*Note:* in particular, `sizeof(bool)`, `sizeof(char16_t)`, `sizeof(char32_t)`, and `sizeof(wchar_t)` are implementation-defined.[75] — *end note*] [*Note:* See 1.277 for the definition of *byte* and 3.2955 for the definition of *object representation*. — *end note*]

1

When applied to a reference or a reference type, the result is the size of the referenced type. When applied to a class, the result is the number of bytes in an object of that class including any padding required for placing objects of that type in an array. The size of a most derived class shall be greater than zero (1.319).

75) `sizeof(bool)` is not required to be `1`.

The result of applying `sizeof` to a base class subobject is the size of the base class type.[76] When applied to an array, the result is the total number of bytes in the array. This implies that the size of an array of n elements is n times the size of an element.

1

The `sizeof` operator can be applied to a pointer to a function, but shall not be applied directly to a function.

1

The lvalue-to-rvalue (4.127), array-to-pointer (4.180), and function-to-pointer (4.220) standard conversions are not applied to the operand of `sizeof`.

1

The identifier in a `sizeof...` expression shall name a parameter pack. The `sizeof...` operator yields the number of arguments provided for the parameter pack *identifier*. A `sizeof...` expression is a pack expansion (14.703.1). [*Example:*

```
template<class... Types>
struct count {
  static const std::size_t value = sizeof...(Types);
};
```

— *end example*]

1

The result of `sizeof` and `sizeof...` is a constant of type `std::size_t`. [*Note:* `std::size_t` is defined in the standard header `<cstddef>` (18.2). — *end note*]

5.2221.1 New [expr.new]

1

The *new-expression* attempts to create an object of the *type-id* (8.32) or *new-type-id* to which it is applied. The type of that object is the *allocated type*. This type shall be a complete object type, but not an abstract class type or array thereof (1.319, 3.2955, 10.276). It is implementation-defined whether over-aligned types are supported (3.3924). [*Note:* because references are not objects, references cannot be created by *new-expressions*. — *end note*] [*Note:* the *type-id* may be a cv-qualified type, in which case the object created by the *new-expression* has a cv-qualified type. — *end note*]

new-expression:
  `::`$_{opt}$`new` *new-placement*$_{opt}$ *new-type-id* *new-initializer*$_{opt}$
  `::`$_{opt}$`new` *new-placement*$_{opt}$`(` *type-id* `)` *new-initializer*$_{opt}$

new-placement:
  `(` *expression-list* `)`

new-type-id:
  type-specifier-seq *new-declarator*$_{opt}$

new-declarator:
  ptr-operator *new-declarator*$_{opt}$
  noptr-new-declarator

noptr-new-declarator:
  `[` *expression* `]` *attribute-specifier-seq*$_{opt}$
  noptr-new-declarator `[` *constant-expression* `]` *attribute-specifier-seq*$_{opt}$

new-initializer:
  `(` *expression-list*$_{opt}$`)`
  braced-init-list

76) The actual size of a base class subobject may be less than the result of applying `sizeof` to the subobject, due to virtual base classes and less strict padding requirements on base class subobjects.

Entities created by a *new-expression* have dynamic storage duration (3.2331.1). [*Note:* the lifetime of such an entity is not necessarily restricted to the scope in which it is created. — *end note*] If the entity is a non-array object, the *new-expression* returns a pointer to the object created. If it is an array, the *new-expression* returns a pointer to the initial element of the array.

1

If the `auto` *type-specifier* appears in the *type-specifier-seq* of a *new-type-id* or *type-id* of a *new-expression*, the *new-expression* shall contain a *new-initializer* of the form

`(` *assignment-expression* `)`

The allocated type is deduced from the *new-initializer* as follows: Let `e` be the *assignment-expression* in the *new-initializer* and `T` be the *new-type-id* or *type-id* of the *new-expression*, then the allocated type is the type deduced for the variable `x` in the invented declaration (7.832.0.1):

```
T x(e);
```

[*Example:*

```
new auto(1);                    // allocated type is int
auto x = new auto('a');         // allocated type is char, x is of type char*
```

— *end example*]

1

The *new-type-id* in a *new-expression* is the longest possible sequence of *new-declarator*s. [*Note:* this prevents ambiguities between the declarator operators `&`, `&&`, `*`, and `[]` and their expression counterparts. — *end note*] [*Example:*

```
new int * i;                    // syntax error: parsed as (new int*) i, not as (new int)*i
```

The `*` is the pointer declarator and not the multiplication operator. — *end example*]

1

[*Note:* parentheses in a *new-type-id* of a *new-expression* can have surprising effects. [*Example:*

```
new int(*[10])();               // error
```

is ill-formed because the binding is

```
(new int) (*[10])();            // error
```

Instead, the explicitly parenthesized version of the `new` operator can be used to create objects of compound types (3.3568.1):

```
new (int (*[10])());
```

allocates an array of `10` pointers to functions (taking no argument and returning `int`. — *end example*] — *end note*]

1

When the allocated object is an array (that is, the *noptr-new-declarator* syntax is used or the *new-type-id* or *type-id* denotes an array type), the *new-expression* yields a pointer to the initial element (if any) of the array. [*Note:* both `new int` and `new int[10]` have type `int*` and the type of `new int[i][10]` is `int (*)[10]` — *end note*] The *attribute-specifier-seq* in a *noptr-new-declarator* appertains to the associated array type.

1

Every *constant-expression* in a *noptr-new-declarator* shall be a converted constant expression (5.3643) of type `std::size_t` and shall evaluate to a strictly positive value. The *expression* in a *noptr-new-declarator*

is implicitly converted to `std::size_t`. [*Example:* given the definition `int n = 42`, `new float[n][5]` is well-formed (because `n` is the *expression* of a *noptr-new-declarator*), but `new float[5][n]` is ill-formed (because `n` is not a constant expression). — *end example*]

1

The *expression* in a *noptr-new-declarator* is erroneous if:

— the expression is of non-class type and its value before converting to `std::size_t` is less than zero;

— the expression is of class type and its value before application of the second standard conversion (13.844.0.0.1)[77] is less than zero;

— its value is such that the size of the allocated object would exceed the implementation-defined limit (annex B); or

— the *new-initializer* is a *braced-init-list* and the number of array elements for which initializers are provided (including the terminating `'\0'` in a string literal (2.453.1)) exceeds the number of elements to initialize.

If the *expression*, after converting to `std::size_t`, is a core constant expression and the expression is erroneous, the program is ill-formed. Otherwise, a *new-expression* with an erroneous expression does not call an allocation function and terminates by throwing an exception of a type that would match a handler (15.146) of type `std::bad_array_new_length` (18.225.0.1). When the value of the *expression* is zero, the allocation function is called to allocate an array with no elements.

1

A *new-expression* may obtain storage for the object by calling an *allocation function* (3.2361.0.1). If the *new-expression* terminates by throwing an exception, it may release storage by calling a deallocation function (3.2428.0.1). If the allocated type is a non-array type, the allocation function's name is `operator new` and the deallocation function's name is `operator delete`. If the allocated type is an array type, the allocation function's name is `operator new[]` and the deallocation function's name is `operator delete[]`. [*Note:* an implementation shall provide default definitions for the global allocation functions (3.2331.1, 18.159.1.1, 18.196.0.1). A C++ program can provide alternative definitions of these functions (17.428.0.3) and/or class-specific versions (12.988). — *end note*]

1

If the *new-expression* begins with a unary `::` operator, the allocation function's name is looked up in the global scope. Otherwise, if the allocated type is a class type `T` or array thereof, the allocation function's name is looked up in the scope of `T`. If this lookup fails to find the name, or if the allocated type is not a class type, the allocation function's name is looked up in the global scope.

1

An implementation is allowed to omit a call to a replaceable global allocation function (18.159.1.1, 18.196.0.1). When it does so, the storage is instead provided by the implementation or provided by extending the allocation of another *new-expression*. The implementation may extend the allocation of a *new-expression* `e1` to provide storage for a *new-expression* `e2` if the following would be true were the allocation not extended:

— the evaluation of `e1` is sequenced before the evaluation of `e2`, and

— `e2` is evaluated whenever `e1` obtains storage, and

— both `e1` and `e2` invoke the same replaceable global allocation function, and

77) If the conversion function returns a signed integer type, the second standard conversion converts to the unsigned type `std::size_t` and thus thwarts any attempt to detect a negative value afterwards.

— if the allocation function invoked by `e1` and `e2` is throwing, any exceptions thrown in the evaluation of either `e1` or `e2` would be first caught in the same handler, and

— the pointer values produced by `e1` and `e2` are operands to evaluated *delete-expression*s, and

— the evaluation of `e2` is sequenced before the evaluation of the *delete-expression* whose operand is the pointer value produced by `e1`.

[*Example:*

```
void mergeable(int x) {
  // These allocations are safe for merging:
  std::unique_ptr<char[]> a{new (std::nothrow) char[8]};
  std::unique_ptr<char[]> b{new (std::nothrow) char[8]};
  std::unique_ptr<char[]> c{new (std::nothrow) char[x]};

  g(a.get(), b.get(), c.get());
}

void unmergeable(int x) {
  std::unique_ptr<char[]> a{new char[8]};
  try {
    // Merging this allocation would change its catch handler.
    std::unique_ptr<char[]> b{new char[x]};
  } catch (const std::bad_alloc& e) {
    std::cerr << "Allocation failed: " << e.what() << std::endl;
    throw;
  }
}
```

— *end example*]

1

When a *new-expression* calls an allocation function and that allocation has not been extended, the *new-expression* passes the amount of space requested to the allocation function as the first argument of type `std::size_t`. That argument shall be no less than the size of the object being created; it may be greater than the size of the object being created only if the object is an array. For arrays of `char` and `unsigned char`, the difference between the result of the *new-expression* and the address returned by the allocation function shall be an integral multiple of the strictest fundamental alignment requirement (3.3924) of any object type whose size is no greater than the size of the array being created. [*Note:* Because allocation functions are assumed to return pointers to storage that is appropriately aligned for objects of any type with fundamental alignment, this constraint on array allocation overhead permits the common idiom of allocating character arrays into which objects of other types will later be placed. — *end note*]

1

When a *new-expression* calls an allocation function and that allocation has been extended, the size argument to the allocation call shall be no greater than the sum of the sizes for the omitted calls as specified above, plus the size for the extended call had it not been extended, plus any padding necessary to align the allocated objects within the allocated memory.

1

The *new-placement* syntax is used to supply additional arguments to an allocation function. If used, overload resolution is performed on a function call created by assembling an argument list consisting of the amount of space requested (the first argument) and the expressions in the *new-placement* part of the *new-expression* (the second and succeeding arguments). The first of these arguments has type `std::size_t` and the remaining arguments have the corresponding types of the expressions in the *new-placement*.

1

[*Example:*

— `new T` results in a call of `operator new(sizeof(T))`,

— `new(2,f) T` results in a call of `operator new(sizeof(T),2,f)`,

— `new T[5]` results in a call of `operator new[](sizeof(T)*5+x)`, and

— `new(2,f) T[5]` results in a call of `operator new[](sizeof(T)*5+y,2,f)`.

Here, `x` and `y` are non-negative unspecified values representing array allocation overhead; the result of the *new-expression* will be offset by this amount from the value returned by `operator new[]`. This overhead may be applied in all array *new-expressions*, including those referencing the library function `operator new[](std::size_t, void*)` and other placement allocation functions. The amount of overhead may vary from one invocation of `new` to another. — *end example*]

1

[*Note:* unless an allocation function is declared with a non-throwing *exception-specification* (15.228), it indicates failure to allocate storage by throwing a `std::bad_alloc` exception (Clause 15, 18.223.1.1); it returns a non-null pointer otherwise. If the allocation function is declared with a non-throwing *exception-specification*, it returns null to indicate failure to allocate storage and a non-null pointer otherwise. — *end note*] If the allocation function returns null, initialization shall not be done, the deallocation function shall not be called, and the value of the *new-expression* shall be null.

1

[*Note:* when the allocation function returns a value other than null, it must be a pointer to a block of storage in which space for the object has been reserved. The block of storage is assumed to be appropriately aligned and of the requested size. The address of the created object will not necessarily be the same as that of the block if the object is an array. — *end note*]

1

A *new-expression* that creates an object of type `T` initializes that object as follows:

— If the *new-initializer* is omitted, the object is default-initialized (8.821). [*Note:* If no initialization is performed, the object has an indeterminate value. — *end note*]

— Otherwise, the *new-initializer* is interpreted according to the initialization rules of 8.821 for direct-initialization.

1

The invocation of the allocation function is indeterminately sequenced with respect to the evaluations of expressions in the *new-initializer*. Initialization of the allocated object is sequenced before the value computation of the *new-expression*. It is unspecified whether expressions in the *new-initializer* are evaluated if the allocation function returns the null pointer or exits using an exception.

1

If the *new-expression* creates an object or an array of objects of class type, access and ambiguity control are done for the allocation function, the deallocation function (12.988), and the constructor (12.30). If the *new-expression* creates an array of objects of class type, the destructor is potentially invoked (12.807).

1

If any part of the object initialization described above[78] terminates by throwing an exception, storage has been obtained for the object, and a suitable deallocation function can be found, the deallocation function is

78) This may include evaluating a *new-initializer* and/or calling a constructor.

called to free the memory in which the object was being constructed, after which the exception continues to propagate in the context of the *new-expression*. If no unambiguous matching deallocation function can be found, propagating the exception does not cause the object's memory to be freed. [*Note:* This is appropriate when the called allocation function does not allocate memory; otherwise, it is likely to result in a memory leak. — *end note*]

1 If the *new-expression* begins with a unary `::` operator, the deallocation function's name is looked up in the global scope. Otherwise, if the allocated type is a class type `T` or an array thereof, the deallocation function's name is looked up in the scope of `T`. If this lookup fails to find the name, or if the allocated type is not a class type or array thereof, the deallocation function's name is looked up in the global scope.

2

A declaration of a placement deallocation function matches the declaration of a placement allocation function if it has the same number of parameters and, after parameter transformations (8.360.1), all parameter types except the first are identical. If the lookup finds a single matching deallocation function, that function will be called; otherwise, no deallocation function will be called. If the lookup finds the two-parameter form of a usual deallocation function (3.2428.0.1) and that function, considered as a placement deallocation function, would have been selected as a match for the allocation function, the program is ill-formed. For a non-placement allocation function, the normal deallocation function lookup is used to find the matching deallocation function (5.2455.1) [*Example:*

```
struct S {
  // Placement allocation function:
  static void* operator new(std::size_t, std::size_t);

  // Usual (non-placement) deallocation function:
  static void operator delete(void*, std::size_t);
};

S* p = new (0) S;    // ill-formed: non-placement deallocation function matches
                     // placement allocation function
```

— *end example*]

1

If a *new-expression* calls a deallocation function, it passes the value returned from the allocation function call as the first argument of type `void*`. If a placement deallocation function is called, it is passed the same additional arguments as were passed to the placement allocation function, that is, the same arguments as those specified with the *new-placement* syntax. If the implementation is allowed to make a copy of any argument as part of the call to the allocation function, it is allowed to make a copy (of the same original value) as part of the call to the deallocation function or to reuse the copy made as part of the call to the allocation function. If the copy is elided in one place, it need not be elided in the other.

5.2455.1 Delete [expr.delete]

1

The *delete-expression* operator destroys a most derived object (1.319) or array created by a *new-expression*.

delete-expression:
  `::`$_{opt}$`delete` *cast-expression*
  `::`$_{opt}$`delete [ ]` *cast-expression*

The first alternative is for non-array objects, and the second is for arrays. Whenever the `delete` keyword is immediately followed by empty square brackets, it shall be interpreted as the second alternative.[79] The

79) A lambda expression with a *lambda-introducer* that consists of empty square brackets can follow the `delete` keyword if

operand shall be of pointer to object type or of class type. If of class type, the operand is contextually implicitly converted (Clause 4) to a pointer to object type.[80] The *delete-expression*'s result has type `void`.

1

If the operand has a class type, the operand is converted to a pointer type by calling the above-mentioned conversion function, and the converted operand is used in place of the original operand for the remainder of this section. In the first alternative (*delete object*), the value of the operand of `delete` may be a null pointer value, a pointer to a non-array object created by a previous *new-expression*, or a pointer to a subobject (1.319) representing a base class of such an object (Clause 10). If not, the behavior is undefined. In the second alternative (*delete array*), the value of the operand of `delete` may be a null pointer value or a pointer value that resulted from a previous array *new-expression*.[81] If not, the behavior is undefined. [*Note:* this means that the syntax of the *delete-expression* must match the type of the object allocated by `new`, not the syntax of the *new-expression*. — *end note*] [*Note:* a pointer to a `const` type can be the operand of a *delete-expression*; it is not necessary to cast away the constness (5.1871.1) of the pointer expression before it is used as the operand of the *delete-expression*. — *end note*]

1

In the first alternative (*delete object*), if the static type of the object to be deleted is different from its dynamic type, the static type shall be a base class of the dynamic type of the object to be deleted and the static type shall have a virtual destructor or the behavior is undefined. In the second alternative (*delete array*) if the dynamic type of the object to be deleted differs from its static type, the behavior is undefined.

1

The *cast-expression* in a *delete-expression* shall be evaluated exactly once.

1

If the object being deleted has incomplete class type at the point of deletion and the complete class has a non-trivial destructor or a deallocation function, the behavior is undefined.

1

If the value of the operand of the *delete-expression* is not a null pointer value, the *delete-expression* will invoke the destructor (if any) for the object or the elements of the array being deleted. In the case of an array, the elements will be destroyed in order of decreasing address (that is, in reverse order of the completion of their constructor; see 12.1026.1).

1

If the value of the operand of the *delete-expression* is not a null pointer value, then:

— If the allocation call for the *new-expression* for the object to be deleted was not omitted and the allocation was not extended (5.2221.1), the *delete-expression* shall call a deallocation function (3.2428.0.1). The value returned from the allocation call of the *new-expression* shall be passed as the first argument to the deallocation function.

— Otherwise, if the allocation was extended or was provided by extending the allocation of another *new-expression*, and the *delete-expression* for every other pointer value produced by a *new-expression* that had storage provided by the extended *new-expression* has been evaluated, the *delete-expression* shall call a deallocation function. The value returned from the allocation call of the extended *new-expression* shall be passed as the first argument to the deallocation function.

— Otherwise, the *delete-expression* will not call a *deallocation function* (3.2428.0.1).

---

the lambda expression is enclosed in parentheses.

80) This implies that an object cannot be deleted using a pointer of type `void*` because `void` is not an object type.

81) For non-zero-length arrays, this is the same as a pointer to the first element of the array created by that *new-expression*. Zero-length arrays do not have a first element.

Otherwise, it is unspecified whether the deallocation function will be called. [*Note:* The deallocation function is called regardless of whether the destructor for the object or some element of the array throws an exception. — *end note*]

1 [*Note:* An implementation provides default definitions of the global deallocation functions `operator delete()` for non-arrays (18.159.1.1) and `operator delete[]()` for arrays (18.196.0.1). A C++ program can provide alternative definitions of these functions (17.428.0.3), and/or class-specific versions (12.988). — *end note*]

2

When the keyword `delete` in a *delete-expression* is preceded by the unary `::` operator, the deallocation function's name is looked up in global scope. Otherwise, the lookup considers class-specific deallocation functions (12.988). If no class-specific deallocation function is found, the deallocation function's name is looked up in global scope.

1

If the type is complete and if deallocation function lookup finds both a usual deallocation function with only a pointer parameter and a usual deallocation function with both a pointer parameter and a size parameter, then the selected deallocation function shall be the one with two parameters. Otherwise, the selected deallocation function shall be the function with one parameter.

1

When a *delete-expression* is executed, the selected deallocation function shall be called with the address of the block of storage to be reclaimed as its first argument and (if the two-parameter deallocation function is used) the size of the block as its second argument.[82]

1

Access and ambiguity control are done for both the deallocation function and the destructor (12.807, 12.988).

5.2747.1 Alignof [expr.alignof]

1

An `alignof` expression yields the alignment requirement of its operand type. The operand shall be a *type-id* representing a complete object type, or an array thereof, or a reference to one of those types.

1 The result is an integral constant of type `std::size_t`.

2

When `alignof` is applied to a reference type, the result is the alignment of the referenced type. When `alignof` is applied to an array type, the result is the alignment of the element type.

5.2750.1 `noexcept` operator [expr.unary.noexcept]

1

The `noexcept` operator determines whether the evaluation of its operand, which is an unevaluated operand (Clause 5), can throw an exception (15.7).

noexcept-expression:
`noexcept (` *expression* `)`

1

The result of the `noexcept` operator is a constant of type `bool` and is a prvalue.

1

82) If the static type of the object to be deleted is complete and is different from the dynamic type, and the destructor is not virtual, the size might be incorrect, but that case is already undefined, as stated above.

The result of the `noexcept` operator is `false` if in a potentially-evaluated context the *expression* would contain

— a potentially-evaluated call[83] to a function, member function, function pointer, or member function pointer that does not have a non-throwing *exception-specification* (15.228), unless the call is a constant expression (5.3643),

— a potentially-evaluated *throw-expression* (15.7),

— a potentially-evaluated `dynamic_cast` expression `dynamic_cast<T>(v)`, where `T` is a reference type, that requires a run-time check (5.1295.1), or

— a potentially-evaluated `typeid` expression (5.1393.1) applied to a glvalue expression whose type is a polymorphic class type (10.113).

Otherwise, the result is `true`.

5.2765 Explicit type conversion (cast notation) [expr.cast]

1

The result of the expression `(T)` *cast-expression* is of type `T`. The result is an lvalue if `T` is an lvalue reference type or an rvalue reference to function type and an xvalue if `T` is an rvalue reference to object type; otherwise the result is a prvalue. [*Note:* if `T` is a non-class type that is cv-qualified, the *cv-qualifiers* are discarded when determining the type of the resulting prvalue; see Clause 5. — *end note*]

1

An explicit type conversion can be expressed using functional notation (5.1108.1), a type conversion operator (`dynamic_cast`, `static_cast`, `reinterpret_cast`, `const_cast`), or the *cast* notation.

cast-expression:
  unary-expression
  `(` *type-id* `)` *cast-expression*

1

Any type conversion not mentioned below and not explicitly defined by the user (12.659) is ill-formed.

1

The conversions performed by

— a `const_cast` (5.1871.1),

— a `static_cast` (5.1443.1),

— a `static_cast` followed by a `const_cast`,

— a `reinterpret_cast` (5.1644.1), or

— a `reinterpret_cast` followed by a `const_cast`,

can be performed using the cast notation of explicit type conversion. The same semantic restrictions and behaviors apply, with the exception that in performing a `static_cast` in the following situations the conversion is valid even if the base class is inaccessible:

— a pointer to an object of derived class type or an lvalue or rvalue of derived class type may be explicitly converted to a pointer or reference to an unambiguous base class type, respectively;

— a pointer to member of derived class type may be explicitly converted to a pointer to member of an unambiguous non-virtual base class type;

83) This includes implicit calls such as the call to an allocation function in a *new-expression*.

— a pointer to an object of an unambiguous non-virtual base class type, a glvalue of an unambiguous non-virtual base class type, or a pointer to member of an unambiguous non-virtual base class type may be explicitly converted to a pointer, a reference, or a pointer to member of a derived class type, respectively.

If a conversion can be interpreted in more than one of the ways listed above, the interpretation that appears first in the list is used, even if a cast resulting from that interpretation is ill-formed. If a conversion can be interpreted in more than one way as a `static_cast` followed by a `const_cast`, the conversion is ill-formed. [*Example:*

```
struct A { };
struct I1 : A { };
struct I2 : A { };
struct D : I1, I2 { };
A* foo( D* p ) {
  return (A*)( p ); // ill-formed static_cast interpretation
}
```

— *end example*]

1

The operand of a cast using the cast notation can be a prvalue of type "pointer to incomplete class type". The destination type of a cast using the cast notation can be "pointer to incomplete class type". If both the operand and destination types are class types and one or both are incomplete, it is unspecified whether the `static_cast` or the `reinterpret_cast` interpretation is used, even if there is an inheritance relationship between the two classes. [*Note:* For example, if the classes were defined later in the translation unit, a multi-pass compiler would be permitted to interpret a cast between pointers to the classes as if the class types were complete at the point of the cast. — *end note*]

5.2832 Pointer-to-member operators [expr.mptr.oper]

1

The pointer-to-member operators `->*` and `.*` group left-to-right.

pm-expression:
  cast-expression
  pm-expression `.*` *cast-expression*
  pm-expression `->*` *cast-expression*

1

The binary operator `.*` binds its second operand, which shall be of type "pointer to member of `T`" to its first operand, which shall be of class `T` or of a class of which `T` is an unambiguous and accessible base class. The result is an object or a function of the type specified by the second operand.

1

The binary operator `->*` binds its second operand, which shall be of type "pointer to member of `T`" to its first operand, which shall be of type "pointer to `T`" or "pointer to a class of which `T` is an unambiguous and accessible base class." The expression `E1->*E2` is converted into the equivalent form `(*(E1)).*E2`.

1

Abbreviating *pm-expression*`.*`*cast-expression* as `E1.*E2`, `E1` is called the *object expression*. If the dynamic type of `E1` does not contain the member to which `E2` refers, the behavior is undefined.

1

The restrictions on *cv*-qualification, and the manner in which the *cv*-qualifiers of the operands are combined to produce the *cv*-qualifiers of the result, are the same as the rules for `E1.E2` given in 5.1194.1. [*Note:* it is

not possible to use a pointer to member that refers to a `mutable` member to modify a `const` class object. For example,

```
struct S {
  S() : i(0) { }
  mutable int i;
};
void f()
{
const S cs;
int S::* pm = &S::i;            // pm refers to mutable member S::i
cs.*pm = 88;                    // ill-formed: cs is a const object
}
```

— *end note*]

1

If the result of `.*` or `->*` is a function, then that result can be used only as the operand for the function call operator `()`. [*Example:*

```
(ptr_to_obj->*ptr_to_mfct)(10);
```

calls the member function denoted by `ptr_to_mfct` for the object pointed to by `ptr_to_obj`. — *end example*] In a `.*` expression whose object expression is an rvalue, the program is ill-formed if the second operand is a pointer to member function with *ref-qualifier* `&`. In a `.*` expression whose object expression is an lvalue, the program is ill-formed if the second operand is a pointer to member function with *ref-qualifier* `&&`. The result of a `.*` expression whose second operand is a pointer to a data member is an lvalue if the first operand is an lvalue and an xvalue otherwise. The result of a `.*` expression whose second operand is a pointer to a member function is a prvalue. If the second operand is the null pointer to member value (4.710), the behavior is undefined.

5.2851 Multiplicative operators [expr.mul]

1 The multiplicative operators `*`, `/`, and `%` group left-to-right.

multiplicative-expression:
- *pm-expression*
- *multiplicative-expression* `*` *pm-expression*
- *multiplicative-expression* `/` *pm-expression*
- *multiplicative-expression* `%` *pm-expression*

2

The operands of `*` and `/` shall have arithmetic or unscoped enumeration type; the operands of `%` shall have integral or unscoped enumeration type. The usual arithmetic conversions are performed on the operands and determine the type of the result.

1 The binary `*` operator indicates multiplication.

2

The binary `/` operator yields the quotient, and the binary `%` operator yields the remainder from the division of the first expression by the second. If the second operand of `/` or `%` is zero the behavior is undefined. For integral operands the `/` operator yields the algebraic quotient with any fractional part discarded;[84] if the quotient `a/b` is representable in the type of the result, `(a/b)*b + a%b` is equal to `a`; otherwise, the behavior of both `a/b` and `a%b` is undefined.

84) This is often called truncation towards zero.

5.2882 Additive operators [expr.add]

1

The additive operators + and - group left-to-right. The usual arithmetic conversions are performed for operands of arithmetic or enumeration type.

additive-expression:
multiplicative-expression
additive-expression + *multiplicative-expression*
additive-expression - *multiplicative-expression*

For addition, either both operands shall have arithmetic or unscoped enumeration type, or one operand shall be a pointer to a completely-defined object type and the other shall have integral or unscoped enumeration type.

1

For subtraction, one of the following shall hold:

— both operands have arithmetic or unscoped enumeration type; or

— both operands are pointers to cv-qualified or cv-unqualified versions of the same completely-defined object type; or

— the left operand is a pointer to a completely-defined object type and the right operand has integral or unscoped enumeration type.

1

The result of the binary + operator is the sum of the operands. The result of the binary - operator is the difference resulting from the subtraction of the second operand from the first.

1

For the purposes of these operators, a pointer to a nonarray object behaves the same as a pointer to the first element of an array of length one with the type of the object as its element type.

1

When an expression that has integral type is added to or subtracted from a pointer, the result has the type of the pointer operand. If the pointer operand points to an element of an array object, and the array is large enough, the result points to an element offset from the original element such that the difference of the subscripts of the resulting and original array elements equals the integral expression. In other words, if the expression P points to the i-th element of an array object, the expressions (P)+N (equivalently, N+(P)) and (P)-N (where N has the value n) point to, respectively, the $i + n$-th and $i - n$-th elements of the array object, provided they exist. Moreover, if the expression P points to the last element of an array object, the expression (P)+1 points one past the last element of the array object, and if the expression Q points one past the last element of an array object, the expression (Q)-1 points to the last element of the array object. If both the pointer operand and the result point to elements of the same array object, or one past the last element of the array object, the evaluation shall not produce an overflow; otherwise, the behavior is undefined.

1

When two pointers to elements of the same array object are subtracted, the result is the difference of the subscripts of the two array elements. The type of the result is an implementation-defined signed integral type; this type shall be the same type that is defined as std::ptrdiff_t in the <cstddef> header (18.2). As with any other arithmetic overflow, if the result does not fit in the space provided, the behavior is undefined. In other words, if the expressions P and Q point to, respectively, the i-th and j-th elements of an array object, the expression (P)-(Q) has the value $i - j$ provided the value fits in an object of type std::ptrdiff_t. Moreover, if the expression P points either to an element of an array object or one past the last element of

an array object, and the expression `Q` points to the last element of the same array object, the expression `((Q)+1)-(P)` has the same value as `((Q)-(P))+1` and as `-((P)-((Q)+1))`, and has the value zero if the expression `P` points one past the last element of the array object, even though the expression `(Q)+1` does not point to an element of the array object. Unless both pointers point to elements of the same array object, or one past the last element of the array object, the behavior is undefined.[85]

1

For addition or subtraction, if the expressions `P` or `Q` have type "pointer to *cv* `T`", where `T` is different from the cv-unqualified array element type, the behavior is undefined. [*Note:* In particular, a pointer to a base class cannot be used for pointer arithmetic when the array contains objects of a derived class type. — *end note*]

1

If the value 0 is added to or subtracted from a pointer value, the result compares equal to the original pointer value. If two pointers point to the same object or both point one past the end of the same array or both are null, and the two pointers are subtracted, the result compares equal to the value 0 converted to the type `std::ptrdiff_t`.

5.3085 Shift operators [expr.shift]

1

The shift operators `<<` and `>>` group left-to-right.

shift-expression:
  additive-expression
  shift-expression `<<` *additive-expression*
  shift-expression `>>` *additive-expression*

The operands shall be of integral or unscoped enumeration type and integral promotions are performed. The type of the result is that of the promoted left operand. The behavior is undefined if the right operand is negative, or greater than or equal to the length in bits of the promoted left operand.

1

The value of `E1 << E2` is `E1` left-shifted `E2` bit positions; vacated bits are zero-filled. If `E1` has an unsigned type, the value of the result is $E1 \times 2^{E2}$, reduced modulo one more than the maximum value representable in the result type. Otherwise, if `E1` has a signed type and non-negative value, and $E1 \times 2^{E2}$ is representable in the corresponding unsigned type of the result type, then that value, converted to the result type, is the resulting value; otherwise, the behavior is undefined.

1

The value of `E1 >> E2` is `E1` right-shifted `E2` bit positions. If `E1` has an unsigned type or if `E1` has a signed type and a non-negative value, the value of the result is the integral part of the quotient of $E1/2^{E2}$. If `E1` has a signed type and a negative value, the resulting value is implementation-defined.

5.3203 Relational operators [expr.rel]

1

The relational operators group left-to-right. [*Example:* `a<b<c` means `(a<b)<c` and *not* `(a<b)&&(b<c)`. — *end example*]

85) Another way to approach pointer arithmetic is first to convert the pointer(s) to character pointer(s): In this scheme the integral value of the expression added to or subtracted from the converted pointer is first multiplied by the size of the object originally pointed to, and the resulting pointer is converted back to the original type. For pointer subtraction, the result of the difference between the character pointers is similarly divided by the size of the object originally pointed to.

When viewed in this way, an implementation need only provide one extra byte (which might overlap another object in the program) just after the end of the object in order to satisfy the "one past the last element" requirements.

relational-expression:
shift-expression
relational-expression `<` *shift-expression*
relational-expression `>` *shift-expression*
relational-expression `<=` *shift-expression*
relational-expression `>=` *shift-expression*

The operands shall have arithmetic, enumeration, or pointer type. The operators `<` (less than), `>` (greater than), `<=` (less than or equal to), and `>=` (greater than or equal to) all yield `false` or `true`. The type of the result is `bool`.

1

The usual arithmetic conversions are performed on operands of arithmetic or enumeration type. If both operands are pointers, pointer conversions (4.579) and qualification conversions (4.246) are performed to bring them to their composite pointer type (Clause 5). After conversions, the operands shall have the same type.

1

Comparing pointers to objects is defined as follows:

— If two pointers point to different elements of the same array, or to subobjects thereof, the pointer to the element with the higher subscript compares greater.

— If one pointer points to an element of an array, or to a subobject thereof, and another pointer points one past the last element of the array, the latter pointer compares greater.

— If two pointers point to different non-static data members of the same object, or to subobjects of such members, recursively, the pointer to the later declared member compares greater provided the two members have the same access control (Clause 11) and provided their class is not a union.

1

If two operands `p` and `q` compare equal (5.3247), `p<=q` and `p>=q` both yield `true` and `p<q` and `p>q` both yield `false`. Otherwise, if a pointer `p` compares greater than a pointer `q`, `p>=q`, `p>q`, `q<=p`, and `q<p` all yield `true` and `p<=q`, `p<q`, `q>=p`, and `q>p` all yield `false`. Otherwise, the result of each of the operators is unspecified.

1

If both operands (after conversions) are of arithmetic or enumeration type, each of the operators shall yield `true` if the specified relationship is true and `false` if it is false.

5.3247 Equality operators [expr.eq]

equality-expression:
relational-expression
equality-expression `==` *relational-expression*
equality-expression `!=` *relational-expression*

1

The `==` (equal to) and the `!=` (not equal to) operators group left-to-right. The operands shall have arithmetic, enumeration, pointer, or pointer to member type, or type `std::nullptr_t`. The operators `==` and `!=` both yield `true` or `false`, i.e., a result of type `bool`. In each case below, the operands shall have the same type after the specified conversions have been applied.

1

If at least one of the operands is a pointer, pointer conversions (4.579) and qualification conversions (4.246) are performed on both operands to bring them to their composite pointer type (Clause 5). Comparing pointers is defined as follows: Two pointers compare equal if they are both null, both point to the same function, or both represent the same address (3.3568.1), otherwise they compare unequal.

1

If at least one of the operands is a pointer to member, pointer to member conversions (4.710) and qualification conversions (4.246) are performed on both operands to bring them to their composite pointer type (Clause 5). Comparing pointers to members is defined as follows:

— If two pointers to members are both the null member pointer value, they compare equal.

— If only one of two pointers to members is the null member pointer value, they compare unequal.

— If either is a pointer to a virtual member function, the result is unspecified.

— If one refers to a member of class `C1` and the other refers to a member of a different class `C2`, where neither is a base class of the other, the result is unspecified. [*Example:*

```
struct A {};
struct B : A { int x; };
struct C : A { int x; };

int A::*bx = (int(A::*))&B::x;
int A::*cx = (int(A::*))&C::x;

bool b1 = (bx == cx);    // unspecified
```

— *end example*]

— Otherwise, two pointers to members compare equal if they would refer to the same member of the same most derived object (1.319) or the same subobject if indirection with a hypothetical object of the associated class type were performed, otherwise they compare unequal. [*Example:*

```
struct B {
  int f();
};
struct L : B { };
struct R : B { };
struct D : L, R { };

int (B::*pb)() = &B::f;
int (L::*pl)() = pb;
int (R::*pr)() = pb;
int (D::*pdl)() = pl;
int (D::*pdr)() = pr;
bool x = (pdl == pdr);          // false
bool y = (pb == pl);            // true
```

— *end example*]

1 Two operands of type `std::nullptr_t` or one operand of type `std::nullptr_t` and the other a null pointer constant compare equal.

2 If two operands compare equal, the result is `true` for the `==` operator and `false` for the `!=` operator. If two operands compare unequal, the result is `false` for the `==` operator and `true` for the `!=` operator. Otherwise, the result of each of the operators is unspecified.

3

If both operands are of arithmetic or enumeration type, the usual arithmetic conversions are performed on both operands; each of the operators shall yield `true` if the specified relationship is true and `false` if it is false.

5.3274 Bitwise AND operator [expr.bit.and]

and-expression:
equality-expression
and-expression `&` *equality-expression*

1

The usual arithmetic conversions are performed; the result is the bitwise AND function of the operands. The operator applies only to integral or unscoped enumeration operands.

5.3279 Bitwise exclusive OR operator [expr.xor]

exclusive-or-expression:
and-expression
exclusive-or-expression `^` *and-expression*

1

The usual arithmetic conversions are performed; the result is the bitwise exclusive OR function of the operands. The operator applies only to integral or unscoped enumeration operands.

5.3282 Bitwise inclusive OR operator [expr.or]

inclusive-or-expression:
exclusive-or-expression
inclusive-or-expression `|` *exclusive-or-expression*

1

The usual arithmetic conversions are performed; the result is the bitwise inclusive OR function of its operands. The operator applies only to integral or unscoped enumeration operands.

5.3286 Logical AND operator [expr.log.and]

logical-and-expression:
inclusive-or-expression
logical-and-expression `&&` *inclusive-or-expression*

1

The `&&` operator groups left-to-right. The operands are both contextually converted to `bool` (Clause 4). The result is `true` if both operands are `true` and `false` otherwise. Unlike `&`, `&&` guarantees left-to-right evaluation: the second operand is not evaluated if the first operand is `false`.

1

The result is a `bool`. If the second expression is evaluated, every value computation and side effect associated with the first expression is sequenced before every value computation and side effect associated with the second expression.

5.3322 Logical OR operator [expr.log.or]

logical-or-expression:
logical-and-expression
logical-or-expression `||` *logical-and-expression*

1

The `||` operator groups left-to-right. The operands are both contextually converted to `bool` (Clause 4). It returns `true` if either of its operands is `true`, and `false` otherwise. Unlike `|`, `||` guarantees left-to-right evaluation; moreover, the second operand is not evaluated if the first operand evaluates to `true`.

1 The result is a `bool`. If the second expression is evaluated, every value computation and side effect associated with the first expression is sequenced before every value computation and side effect associated with the second expression.

5.3337 Conditional operator [expr.cond]

conditional-expression:
logical-or-expression
logical-or-expression `?` *expression* `:` *assignment-expression*

1

Conditional expressions group right-to-left. The first expression is contextually converted to `bool` (Clause 4). It is evaluated and if it is `true`, the result of the conditional expression is the value of the second expression, otherwise that of the third expression. Only one of the second and third expressions is evaluated. Every value computation and side effect associated with the first expression is sequenced before every value computation and side effect associated with the second or third expression.

1

If either the second or the third operand has type `void`, one of the following shall hold:

— The second or the third operand (but not both) is a (possibly parenthesized) *throw-expression* (15.7); the result is of the type and value category of the other.

— Both the second and the third operands have type `void`; the result is of type `void` and is a prvalue. [*Note:* This includes the case where both operands are *throw-expressions*. — *end note*]

1

Otherwise, if the second and third operand have different types and either has (possibly cv-qualified) class type, or if both are glvalues of the same value category and the same type except for cv-qualification, an attempt is made to convert each of those operands to the type of the other. The process for determining whether an operand expression `E1` of type `T1` can be converted to match an operand expression `E2` of type `T2` is defined as follows:

— If `E2` is an lvalue: `E1` can be converted to match `E2` if `E1` can be implicitly converted (Clause 4) to the type "lvalue reference to `T2`", subject to the constraint that in the conversion the reference must bind directly (8.2156.1) to an lvalue.

— If `E2` is an xvalue: `E1` can be converted to match `E2` if `E1` can be implicitly converted to the type "rvalue reference to `T2`", subject to the constraint that the reference must bind directly.

— If `E2` is a prvalue or if neither of the conversions above can be done and at least one of the operands has (possibly cv-qualified) class type:
  — if `E1` and `E2` have class type, and the underlying class types are the same or one is a base class of the other: `E1` can be converted to match `E2` if the class of `T2` is the same type as, or a base class of, the class of `T1`, and the cv-qualification of `T2` is the same cv-qualification as, or a greater cv-qualification than, the cv-qualification of `T1`. If the conversion is applied, `E1` is changed to a prvalue of type `T2` by copy-initializing a temporary of type `T2` from `E1` and using that temporary as the converted operand.
  — Otherwise (i.e., if `E1` or `E2` has a nonclass type, or if they both have class types but the underlying classes are not either the same or one a base class of the other): `E1` can be converted to match `E2` if `E1` can be implicitly converted to the type that expression `E2` would have if `E2` were converted to a prvalue (or the type it has, if `E2` is a prvalue).

Using this process, it is determined whether the second operand can be converted to match the third operand, and whether the third operand can be converted to match the second operand. If both can be converted, or one can be converted but the conversion is ambiguous, the program is ill-formed. If neither can be converted, the operands are left unchanged and further checking is performed as described below. If exactly one conversion is possible, that conversion is applied to the chosen operand and the converted operand is used in place of the original operand for the remainder of this section.

1

If the second and third operands are glvalues of the same value category and have the same type, the result is of that type and value category and it is a bit-field if the second or the third operand is a bit-field, or if both are bit-fields.

1

Otherwise, the result is a prvalue. If the second and third operands do not have the same type, and either has (possibly cv-qualified) class type, overload resolution is used to determine the conversions (if any) to be applied to the operands (13.264.0.1, 13.1258). If the overload resolution fails, the program is ill-formed. Otherwise, the conversions thus determined are applied, and the converted operands are used in place of the original operands for the remainder of this section.

1

Lvalue-to-rvalue (4.127), array-to-pointer (4.180), and function-to-pointer (4.220) standard conversions are performed on the second and third operands. After those conversions, one of the following shall hold:

— The second and third operands have the same type; the result is of that type. If the operands have class type, the result is a prvalue temporary of the result type, which is copy-initialized from either the second operand or the third operand depending on the value of the first operand.

— The second and third operands have arithmetic or enumeration type; the usual arithmetic conversions are performed to bring them to a common type, and the result is of that type.

— One or both of the second and third operands have pointer type; pointer conversions (4.579) and qualification conversions (4.246) are performed to bring them to their composite pointer type (Clause 5). The result is of the composite pointer type.

— One or both of the second and third operands have pointer to member type; pointer to member conversions (4.710) and qualification conversions (4.246) are performed to bring them to their composite pointer type (Clause 5). The result is of the composite pointer type.

— Both the second and third operands have type `std::nullptr_t` or one has that type and the other is a null pointer constant. The result is of type `std::nullptr_t`.

5.3483 Assignment and compound assignment operators [expr.ass]

1

The assignment operator (`=`) and the compound assignment operators all group right-to-left. All require a modifiable lvalue as their left operand and return an lvalue referring to the left operand. The result in all cases is a bit-field if the left operand is a bit-field. In all cases, the assignment is sequenced after the value computation of the right and left operands, and before the value computation of the assignment expression. With respect to an indeterminately-sequenced function call, the operation of a compound assignment is a single evaluation. [*Note:* Therefore, a function call shall not intervene between the lvalue-to-rvalue conversion and the side effect associated with any single compound assignment operator. — *end note*]

assignment-expression:
  conditional-expression
  logical-or-expression assignment-operator initializer-clause
  throw-expression

assignment-operator: one of
  `= *= /= %= += -= >>= <<= &= ^= |=`

1

In simple assignment (`=`), the value of the expression replaces that of the object referred to by the left operand.

1

If the left operand is not of class type, the expression is implicitly converted (Clause 4) to the cv-unqualified type of the left operand.

1

If the left operand is of class type, the class shall be complete. Assignment to objects of a class is defined by the copy/move assignment operator (12.1577, 13.1178.1).

1 [*Note:* For class objects, assignment is not in general the same as initialization (8.821, 12.30, 12.1011, 12.1577). — *end note*]

2

When the left operand of an assignment operator denotes a reference to `T`, the operation assigns to the object of type `T` denoted by the reference.

1

The behavior of an expression of the form `E1` *op* `= E2` is equivalent to `E1 = E1` *op* `E2` except that `E1` is evaluated only once. In `+=` and `-=`, `E1` shall either have arithmetic type or be a pointer to a possibly cv-qualified completely-defined object type. In all other cases, `E1` shall have arithmetic type.

1

If the value being stored in an object is accessed from another object that overlaps in any way the storage of the first object, then the overlap shall be exact and the two objects shall have the same type, otherwise the behavior is undefined. [*Note:* This restriction applies to the relationship between the left and right sides of the assignment operation; it is not a statement about how the target of the assignment may be aliased in general. See 3.3673. — *end note*]

1

A *braced-init-list* may appear on the right-hand side of

— an assignment to a scalar, in which case the initializer list shall have at most a single element. The meaning of `x={v}`, where `T` is the scalar type of the expression `x`, is that of `x=T{v}`. The meaning of `x={}` is `x=T{}`.

— an assignment to an object of class type, in which case the initializer list is passed as the argument to the assignment operator function selected by overload resolution (13.1178.1, 13.88).

[*Example:*

```
complex<double> z;
z = { 1,2 };              // meaning z.operator=({1,2})
z += { 1, 2 };            // meaning z.operator+=({1,2})
int a, b;
a = b = { 1 };            // meaning a=b=1;
a = { 1 } = b;            // syntax error
```

— *end example*]

5.3602 Comma operator [expr.comma]

1

The comma operator groups left-to-right.

expression:
  assignment-expression
  expression **,** *assignment-expression*

A pair of expressions separated by a comma is evaluated left-to-right; the left expression is a discarded-value expression (Clause 5).[86] Every value computation and side effect associated with the left expression is sequenced before every value computation and side effect associated with the right expression. The type and value of the result are the type and value of the right operand; the result is of the same value category as its right operand, and is a bit-field if its right operand is a glvalue and a bit-field. If the value of the right operand is a temporary (12.306), the result is that temporary.

1

In contexts where comma is given a special meaning, [*Example:* in lists of arguments to functions (5.955.1) and lists of initializers (8.821) — *end example*] the comma operator as described in Clause 5 can appear only in parentheses. [*Example:*

```
f(a, (t=3, t+2), c);
```

has three arguments, the second of which has the value `5`. — *end example*]

5.3643 Constant expressions [expr.const]

1

Certain contexts require expressions that satisfy additional requirements as detailed in this sub-clause; other contexts have different semantics depending on whether or not an expression satisfies these requirements. Expressions that satisfy these requirements are called *constant expressions*. [*Note:* Constant expressions can be evaluated during translation. — *end note*]

constant-expression:
    conditional-expression

1

A *conditional-expression* `e` is a *core constant expression* unless the evaluation of `e`, following the rules of the abstract machine (1.430), would evaluate one of the following expressions:

— `this` (5.398.1), except in a `constexpr` function or a `constexpr` constructor that is being evaluated as part of `e`;

— an invocation of a function other than a `constexpr` constructor for a literal class, a `constexpr` function, or an implicit invocation of a trivial destructor (12.807) [*Note:* Overload resolution (13.88) is applied as usual — *end note*];

— an invocation of an undefined `constexpr` function or an undefined `constexpr` constructor;

— an expression that would exceed the implementation-defined limits (see Annex B);

— an operation that would have undefined behavior [*Note:* including, for example, signed integer overflow (Clause 5), certain pointer arithmetic (5.2882), division by zero (5.2851), or certain shift operations (5.3085) — *end note*];

— a *lambda-expression* (5.509.1);

— an lvalue-to-rvalue conversion (4.127) unless it is applied to

  — a non-volatile glvalue of integral or enumeration type that refers to a non-volatile const object with a preceding initialization, initialized with a constant expression [*Note:* a string literal (2.453.1) corresponds to an array of such objects. — *end note*], or

86) However, an invocation of an overloaded comma operator is an ordinary function call; hence, the evaluations of its argument expressions are unsequenced relative to one another (see 1.430).

  - a non-volatile glvalue that refers to a non-volatile object defined with `constexpr`, or that refers to a non-mutable sub-object of such an object, or
  - a non-volatile glvalue of literal type that refers to a non-volatile object whose lifetime began within the evaluation of `e`;

- an lvalue-to-rvalue conversion (4.127) or modification (5.3483, 5.1264.1, 5.2054.1) that is applied to a glvalue that refers to a non-active member of a union or a subobject thereof;
- an *id-expression* that refers to a variable or data member of reference type unless the reference has a preceding initialization and either
  - it is initialized with a constant expression or
  - it is a non-static data member of an object whose lifetime began within the evaluation of `e`;
- in a *lambda-expression*, a reference to `this` or to a variable with automatic storage duration defined outside that *lambda-expression*, where the reference would be an odr-use (3.91, 5.509.1);
- a conversion from type *cv* `void *` to a pointer-to-object type;
- a dynamic cast (5.1295.1);
- a `reinterpret_cast` (5.1644.1);
- a pseudo-destructor call (5.1181.1);
- modification of an object (5.3483, 5.1264.1, 5.2054.1) unless it is applied to a non-volatile lvalue of literal type that refers to a non-volatile object whose lifetime began within the evaluation of `e`;
- a typeid expression (5.1393.1) whose operand is a glvalue of a polymorphic class type;
- a *new-expression* (5.2221.1);
- a *delete-expression* (5.2455.1);
- a relational (5.3203) or equality (5.3247) operator where the result is unspecified; or
- a *throw-expression* (15.7).

[*Example:*

```
int x;                              // not constant
struct A {
  constexpr A(bool b) : m(b?42:x) { }
  int m;
};
constexpr int v = A(true).m;        // OK: constructor call initializes
                                    // m with the value 42
constexpr int w = A(false).m;       // error: initializer for m is
                                    // x, which is non-constant

constexpr int f1(int k) {
  constexpr int x = k;              // error: x is not initialized by a
                                    // constant expression because lifetime of k
                                    // began outside the initializer of x
  return x;
}
constexpr int f2(int k) {
  int x = k;                        // OK: not required to be a constant expression
```

```
                                        // because x is not constexpr
  return x;
}

constexpr int incr(int &n) {
  return ++n;
}
constexpr int g(int k) {
  constexpr int x = incr(k);            // error: incr(k) is not a core constant
                                        // expression because lifetime of k
                                        // began outside the expression incr(k)
  return x;
}
constexpr int h(int k) {
  int x = incr(k);                      // OK: incr(k) is not required to be a core
                                        // constant expression
  return x;
}
constexpr int y = h(1);                 // OK: initializes y with the value 2
                                        // h(1) is a core constant expression because
                                        // the lifetime of k begins inside h(1)
```

— *end example*]

1

An *integral constant expression* is an expression of integral or unscoped enumeration type, implicitly converted to a prvalue, where the converted expression is a core constant expression. [*Note:* Such expressions may be used as array bounds (8.251.1, 5.2221.1), as bit-field lengths (9.921), as enumerator initializers if the underlying type is not fixed (7.1001), and as alignments (7.1556.1). — *end note*] A *converted constant expression* of type `T` is an expression, implicitly converted to a prvalue of type `T`, where the converted expression is a core constant expression and the implicit conversion sequence contains only user-defined conversions, lvalue-to-rvalue conversions (4.127), integral promotions (4.262), and integral conversions (4.397) other than narrowing conversions (8.2435.1). [*Note:* such expressions may be used in `new` expressions (5.2221.1), as case expressions (6.72.1), as enumerator initializers if the underlying type is fixed (7.1001), as array bounds (8.251.1), and as integral or enumeration non-type template arguments (14.326). — *end note*]

1

A *constant expression* is either a glvalue core constant expression whose value refers to an object with static storage duration or to a function, or a prvalue core constant expression whose value is an object where, for that object and its subobjects:

— each non-static data member of reference type refers to an object with static storage duration or to a function, and

— if the object or subobject is of pointer type, it contains the address of an object with static storage duration, the address past the end of such an object (5.2882), the address of a function, or a null pointer value.

1

[*Note:* Since this International Standard imposes no restrictions on the accuracy of floating-point operations, it is unspecified whether the evaluation of a floating-point expression during translation yields the same result as the evaluation of the same expression (or the same operations on the same values) during program

execution.[87] [*Example:*

```
bool f() {
    char array[1 + int(1 + 0.2 - 0.1 - 0.1)];  // Must be evaluated during translation
    int size = 1 + int(1 + 0.2 - 0.1 - 0.1);   // May be evaluated at runtime
    return sizeof(array) == size;
}
```

It is unspecified whether the value of `f()` will be `true` or `false`. — *end example*] — *end note*]

1

If an expression of literal class type is used in a context where an integral constant expression is required, then that expression is contextually implicitly converted (Clause 4) to an integral or unscoped enumeration type and the selected conversion function shall be `constexpr`. [*Example:*

```
struct A {
  constexpr A(int i) : val(i) { }
  constexpr operator int() const { return val; }
  constexpr operator long() const { return 43; }
private:
  int val;
};
template<int> struct X { };
constexpr A a = 42;
X<a> x;             // OK: unique conversion to int
int ary[a];         // error: ambiguous conversion
```

— *end example*]

87) Nonetheless, implementations are encouraged to provide consistent results, irrespective of whether the evaluation was performed during translation and/or during program execution.

6 Statements [stmt.stmt]

1

Except as indicated, statements are executed in sequence.

statement:
- *labeled-statement*
- *attribute-specifier-seq*$_{opt}$ *expression-statement*
- *attribute-specifier-seq*$_{opt}$ *compound-statement*
- *attribute-specifier-seq*$_{opt}$ *selection-statement*
- *attribute-specifier-seq*$_{opt}$ *iteration-statement*
- *attribute-specifier-seq*$_{opt}$ *jump-statement*
- *declaration-statement*
- *attribute-specifier-seq*$_{opt}$ *try-block*

The optional *attribute-specifier-seq* appertains to the respective statement.

6.3 Labeled statement [stmt.label]

1

A statement can be labeled.

labeled-statement:
- *attribute-specifier-seq*$_{opt}$ *identifier* `:` *statement*
- *attribute-specifier-seq*$_{opt}$`case` *constant-expression* `:` *statement*
- *attribute-specifier-seq*$_{opt}$`default :` *statement*

The optional *attribute-specifier-seq* appertains to the label. An identifier label declares the identifier. The only use of an identifier label is as the target of a `goto`. The scope of a label is the function in which it appears. Labels shall not be redeclared within a function. A label can be used in a `goto` statement before its definition. Labels have their own name space and do not interfere with other identifiers.

1

Case labels and default labels shall occur only in switch statements.

6.9 Expression statement [stmt.expr]

1

Expression statements have the form

expression-statement:
- *expression*$_{opt}$ `;`

The expression is a discarded-value expression (Clause 5). All side effects from an expression statement are completed before the next statement is executed. An expression statement with the expression missing is called a null statement. [*Note:* Most statements are expression statements — usually assignments or function calls. A null statement is useful to carry a label just before the `}` of a compound statement and to supply a null body to an iteration statement such as a `while` statement (6.144.1). — *end note*]

6.15 Compound statement or block [stmt.block]

1

So that several statements can be used where one is expected, the compound statement (also, and equivalently, called "block") is provided.

compound-statement:
  { *statement-seq*$_{opt}$}
statement-seq:
  statement
  statement-seq statement

A compound statement defines a block scope (3.464). [*Note:* A declaration is a statement (6.419). — *end note*]

6.23 Selection statements [stmt.select]

1

Selection statements choose one of several flows of control.

selection-statement:
  `if` (*condition*) *statement*
  `if` (*condition*) *statement* `else` *statement*
  `switch` (*condition*) *statement*
condition:
  expression
  attribute-specifier-seq$_{opt}$ *decl-specifier-seq declarator* `=` *initializer-clause*
  attribute-specifier-seq$_{opt}$ *decl-specifier-seq declarator braced-init-list*

See 8.56 for the optional *attribute-specifier-seq* in a condition. In Clause 6, the term *substatement* refers to the contained statement or statements that appear in the syntax notation. The substatement in a *selection-statement* (each substatement, in the `else` form of the `if` statement) implicitly defines a block scope (3.464). If the substatement in a selection-statement is a single statement and not a *compound-statement,* it is as if it was rewritten to be a compound-statement containing the original substatement. [*Example:*

```
if (x)
  int i;
```

can be equivalently rewritten as

```
if (x) {
  int i;
}
```

Thus after the `if` statement, `i` is no longer in scope. — *end example*]

1

The rules for conditions apply both to *selection-statement*s and to the `for` and `while` statements (6.137). The declarator shall not specify a function or an array. The *decl-specifier-seq* shall not define a class or enumeration. If the `auto` *type-specifier* appears in the *decl-specifier-seq*, the type of the identifier being declared is deduced from the initializer as described in 7.832.0.1.

1

A name introduced by a declaration in a condition (either introduced by the *decl-specifier-seq* or the declarator of the condition) is in scope from its point of declaration until the end of the substatements controlled by the condition. If the name is re-declared in the outermost block of a substatement controlled by the condition, the declaration that re-declares the name is ill-formed. [*Example:*

```
if (int x = f()) {
  int x;            // ill-formed, redeclaration of x
}
else {
  int x;            // ill-formed, redeclaration of x
}
```

— *end example*]

1

The value of a condition that is an initialized declaration in a statement other than a `switch` statement is the value of the declared variable contextually converted to `bool` (Clause 4). If that conversion is ill-formed, the program is ill-formed. The value of a condition that is an initialized declaration in a `switch` statement is the value of the declared variable if it has integral or enumeration type, or of that variable implicitly converted to integral or enumeration type otherwise. The value of a condition that is an expression is the value of the expression, contextually converted to `bool` for statements other than `switch`; if that conversion is ill-formed, the program is ill-formed. The value of the condition will be referred to as simply "the condition" where the usage is unambiguous.

1 If a condition can be syntactically resolved as either an expression or the declaration of a block-scope name, it is interpreted as a declaration.

2

In the *decl-specifier-seq* of a *condition*, each *decl-specifier* shall be either a *type-specifier* or `constexpr`.

6.66.1 The `if` statement [stmt.if]

1

If the condition (6.23) yields `true` the first substatement is executed. If the `else` part of the selection statement is present and the condition yields `false`, the second substatement is executed. If the first substatement is reached via a label, the condition is not evaluated and the second substatement is not executed. In the second form of `if` statement (the one including `else`), if the first substatement is also an `if` statement then that inner `if` statement shall contain an `else` part.[88]

6.72.1 The `switch` statement [stmt.switch]

1

The `switch` statement causes control to be transferred to one of several statements depending on the value of a condition.

1

The condition shall be of integral type, enumeration type, or class type. If of class type, the condition is contextually implicitly converted (Clause 4) to an integral or enumeration type. If the (possibly converted) type is subject to integral promotions (4.262), the condition is converted to the promoted type. Any statement within the `switch` statement can be labeled with one or more case labels as follows:

`case` *constant-expression* `:`

where the *constant-expression* shall be a converted constant expression (5.3643) of the adjusted type of the switch condition. No two of the case constants in the same switch shall have the same value after conversion.

1 There shall be at most one label of the form

```
default :
```

within a `switch` statement.

2

Switch statements can be nested; a `case` or `default` label is associated with the smallest switch enclosing it.

1

88) In other words, the `else` is associated with the nearest un-elsed `if`.

When the `switch` statement is executed, its condition is evaluated and compared with each case constant. If one of the case constants is equal to the value of the condition, control is passed to the statement following the matched case label. If no case constant matches the condition, and if there is a `default` label, control passes to the statement labeled by the default label. If no case matches and if there is no `default` then none of the statements in the switch is executed.

1

`case` and `default` labels in themselves do not alter the flow of control, which continues unimpeded across such labels. To exit from a switch, see `break`, 6.263.1. [*Note:* Usually, the substatement that is the subject of a switch is compound and `case` and `default` labels appear on the top-level statements contained within the (compound) substatement, but this is not required. Declarations can appear in the substatement of a *switch-statement*. — *end note*]

6.137 Iteration statements [stmt.iter]

1

Iteration statements specify looping.

iteration-statement:
- `while` `(` *condition* `)` *statement*
- `do` *statement* `while` `(` *expression* `)` `;`
- `for` `(` *for-init-statement condition*$_{opt}$`;` *expression*$_{opt}$`)` *statement*
- `for` `(` *for-range-declaration* `:` *for-range-initializer* `)` *statement*

for-init-statement:
- *expression-statement*
- *simple-declaration*

for-range-declaration:
- *attribute-specifier-seq*$_{opt}$ *decl-specifier-seq declarator*

for-range-initializer:
- *expression*
- *braced-init-list*

See 8.56 for the optional *attribute-specifier-seq* in a *for-range-declaration*. [*Note:* A *for-init-statement* ends with a semicolon. — *end note*]

1

The substatement in an *iteration-statement* implicitly defines a block scope (3.464) which is entered and exited each time through the loop.

If the substatement in an iteration-statement is a single statement and not a *compound-statement,* it is as if it was rewritten to be a compound-statement containing the original statement. [*Example:*

```
while (--x >= 0)
  int i;
```

can be equivalently rewritten as

```
while (--x >= 0) {
  int i;
}
```

1 Thus after the `while` statement, `i` is no longer in scope. — *end example*]

2 [*Note:* The requirements on conditions in iteration statements are described in 6.23. — *end note*]

6.144.1 The `while` statement [stmt.while]

1

In the `while` statement the substatement is executed repeatedly until the value of the condition (6.23) becomes `false`. The test takes place before each execution of the substatement.

1

When the condition of a `while` statement is a declaration, the scope of the variable that is declared extends from its point of declaration (3.536.1) to the end of the `while` statement. A `while` statement of the form

```
while (T t = x) statement
```

is equivalent to

```
label:
{                       // start of condition scope
  T t = x;
  if (t) {
    statement
    goto label;
  }
}                       // end of condition scope
```

The variable created in a condition is destroyed and created with each iteration of the loop. [*Example:*

```
struct A {
  int val;
  A(int i) : val(i) { }
  ~A() { }
  operator bool() { return val != 0; }
};
int i = 1;
while (A a = i) {
  // ...
  i = 0;
}
```

In the while-loop, the constructor and destructor are each called twice, once for the condition that succeeds and once for the condition that fails. — *end example*]

6.149.1 The `do` statement [stmt.do]

1 The expression is contextually converted to `bool` (Clause 4); if that conversion is ill-formed, the program is ill-formed.

2

In the `do` statement the substatement is executed repeatedly until the value of the expression becomes `false`. The test takes place after each execution of the statement.

6.150.1 The `for` statement [stmt.for]

1

The `for` statement

`for (` *for-init-statement condition*$_{opt}$ `;` *expression*$_{opt}$ `)` *statement*

is equivalent to

```
{
    for-init-statement
    while ( condition ) {
        statement
        expression ;
    }
}
```

except that names declared in the *for-init-statement* are in the same declarative region as those declared in the condition, and except that a `continue` in statement (not enclosed in another iteration statement) will execute expression before re-evaluating condition. [*Note:* Thus the first statement specifies initialization for the loop; the condition (6.23) specifies a test, made before each iteration, such that the loop is exited when the condition becomes `false`; the expression often specifies incrementing that is done after each iteration. — *end note*]

1

Either or both of the condition and the expression can be omitted. A missing condition makes the implied `while` clause equivalent to `while(true)`.

1

If the *for-init-statement* is a declaration, the scope of the name(s) declared extends to the end of the `for` statement. [*Example:*

```
int i = 42;
int a[10];

for (int i = 0; i < 10; i++)
  a[i] = i;

int j = i;          // j = 42
```

— *end example*]

6.165.1 The range-based `for` statement [stmt.ranged]

1

For a range-based `for` statement of the form

`for` (*for-range-declaration : expression*) *statement*

let *range-init* be equivalent to the *expression* surrounded by parentheses[89]

(*expression*)

and for a range-based `for` statement of the form

`for` (*for-range-declaration* : *braced-init-list*) *statement*

let *range-init* be equivalent to the *braced-init-list*. In each case, a range-based `for` statement is equivalent to

```
{
  auto && __range = range-init;
  for ( auto __begin = begin-expr,
            __end = end-expr;
        __begin != __end;
        ++__begin ) {
```

89) this ensures that a top-level comma operator cannot be reinterpreted as a delimiter between *init-declarator*s in the declaration of `__range`.

```
    for-range-declaration = *__begin;
    statement
  }
}
```

where `__range`, `__begin`, and `__end` are variables defined for exposition only, and `_RangeT` is the type of the expression, and *begin-expr* and *end-expr* are determined as follows:

— if `_RangeT` is an array type, *begin-expr* and *end-expr* are `__range` and `__range + __bound`, respectively, where `__bound` is the array bound. If `_RangeT` is an array of unknown size or an array of incomplete type, the program is ill-formed;

— if `_RangeT` is a class type, the *unqualified-id*s `begin` and `end` are looked up in the scope of class `_RangeT` as if by class member access lookup (3.1423.1), and if either (or both) finds at least one declaration, *begin-expr* and *end-expr* are `__range.begin()` and `__range.end()`, respectively;

— otherwise, *begin-expr* and *end-expr* are `begin(__range)` and `end(__range)`, respectively, where `begin` and `end` are looked up in the associated namespaces (3.1092.1). [*Note:* Ordinary unqualified lookup (3.952.1) is not performed. — *end note*]

[*Example:*

```
int array[5] = { 1, 2, 3, 4, 5 };
for (int& x : array)
  x *= 2;
```

— *end example*]

1

In the *decl-specifier-seq* of a *for-range-declaration*, each *decl-specifier* shall be either a *type-specifier* or `constexpr`. The *decl-specifier-seq* shall not define a class or enumeration.

6.236 Jump statements [stmt.jump]

1 Jump statements unconditionally transfer control.

jump-statement:
- `break ;`
- `continue ;`
- `return` *expression*$_{opt}$ `;`
- `return` *braced-init-list* `;`
- `goto` *identifier* `;`

2

On exit from a scope (however accomplished), objects with automatic storage duration (3.2301.1) that have been constructed in that scope are destroyed in the reverse order of their construction. [*Note:* For temporaries, see 12.306. — *end note*] Transfer out of a loop, out of a block, or back past an initialized variable with automatic storage duration involves the destruction of objects with automatic storage duration that are in scope at the point transferred from but not at the point transferred to. (See 6.419 for transfers into blocks). [*Note:* However, the program can be terminated (by calling `std::exit()` or `std::abort()` (18.127), for example) without destroying class objects with automatic storage duration. — *end note*]

6.263.1 The `break` statement [stmt.break]

1

The `break` statement shall occur only in an *iteration-statement* or a `switch` statement and causes termination of the smallest enclosing *iteration-statement* or `switch` statement; control passes to the statement following the terminated statement, if any.

6.270.1 The `continue` statement [stmt.cont]

1 The `continue` statement shall occur only in an *iteration-statement* and causes control to pass to the loop-continuation portion of the smallest enclosing *iteration-statement*, that is, to the end of the loop. More precisely, in each of the statements

```
while (foo) {
  {
    // ...
  }
contin: ;
}
```

```
do {
  {
    // ...
  }
contin: ;
} while (foo);
```

```
for (;;) {
  {
    // ...
  }
contin: ;
}
```

a `continue` not contained in an enclosed iteration statement is equivalent to `goto contin`.

6.270.2 The `return` statement [stmt.return]

1

A function returns to its caller by the `return` statement.

1

A return statement with neither an *expression* nor a *braced-init-list* can be used only in functions that do not return a value, that is, a function with the return type *cv* `void`, a constructor (12.30), or a destructor (12.807). A return statement with an expression of non-void type can be used only in functions returning a value; the value of the expression is returned to the caller of the function. The value of the expression is implicitly converted to the return type of the function in which it appears. A return statement can involve the construction and copy or move of a temporary object (12.306). [*Note:* A copy or move operation associated with a return statement may be elided or considered as an rvalue for the purpose of overload resolution in selecting a constructor (12.1577). — *end note*] A return statement with a *braced-init-list* initializes the object or reference to be returned from the function by copy-list-initialization (8.2435.1) from the specified initializer list. [*Example:*

```
std::pair<std::string,int> f(const char* p, int x) {
  return {p,x};
}
```

— *end example*]

Flowing off the end of a function is equivalent to a `return` with no value; this results in undefined behavior in a value-returning function.

1

A return statement with an expression of type `void` can be used only in functions with a return type of *cv* `void`; the expression is evaluated just before the function returns to its caller.

6.413.1 The `goto` statement [stmt.goto]

1

The `goto` statement unconditionally transfers control to the statement labeled by the identifier. The identifier shall be a label (6.3) located in the current function.

6.419 Declaration statement [stmt.dcl]

1

A declaration statement introduces one or more new identifiers into a block; it has the form

declaration-statement:
block-declaration

If an identifier introduced by a declaration was previously declared in an outer block, the outer declaration is hidden for the remainder of the block, after which it resumes its force.

1

Variables with automatic storage duration (3.2301.1) are initialized each time their *declaration-statement* is executed. Variables with automatic storage duration declared in the block are destroyed on exit from the block (6.236).

1

It is possible to transfer into a block, but not in a way that bypasses declarations with initialization. A program that jumps[90] from a point where a variable with automatic storage duration is not in scope to a point where it is in scope is ill-formed unless the variable has scalar type, class type with a trivial default constructor and a trivial destructor, a cv-qualified version of one of these types, or an array of one of the preceding types and is declared without an initializer (8.821). [*Example:*

```
void f() {
  // ...
  goto lx;          // ill-formed: jump into scope of a
  // ...
ly:
  X a = 1;
  // ...
lx:
  goto ly;          // OK, jump implies destructor
                    // call for a followed by construction
                    // again immediately following label ly
}
```

— *end example*]

1

The zero-initialization (8.821) of all block-scope variables with static storage duration (3.2242.1) or thread storage duration (3.2291.1) is performed before any other initialization takes place. Constant initialization (3.1937.1) of a block-scope entity with static storage duration, if applicable, is performed before its block is first entered. An implementation is permitted to perform early initialization of other block-scope variables with static or thread storage duration under the same conditions that an implementation is permitted to statically initialize a variable with static or thread storage duration in namespace scope (3.1937.1). Otherwise such a variable is initialized the first time control passes through its declaration; such a variable is considered initialized upon the completion of its initialization. If the initialization exits by throwing an exception, the initialization is not complete, so it will be tried again the next time control enters the declaration. If control enters the declaration concurrently while the variable is being initialized, the concurrent execution shall wait for completion of the initialization.[91] If control re-enters the declaration recursively while the variable is being initialized, the behavior is undefined. [*Example:*

```
int foo(int i) {
  static int s = foo(2*i);      // recursive call - undefined
  return i+1;
}
```

— *end example*]

1

90) The transfer from the condition of a `switch` statement to a `case` label is considered a jump in this respect.
91) The implementation must not introduce any deadlock around execution of the initializer.

The destructor for a block-scope object with static or thread storage duration will be executed if and only if it was constructed. [*Note:* 3.2200.1 describes the order in which block-scope objects with static and thread storage duration are destroyed. — *end note*]

6.556 Ambiguity resolution [stmt.ambig]

1

There is an ambiguity in the grammar involving *expression-statement*s and *declaration*s: An *expression-statement* with a function-style explicit type conversion (5.1108.1) as its leftmost subexpression can be indistinguishable from a *declaration* where the first *declarator* starts with a `(`. In those cases the *statement* is a *declaration*.

1

[*Note:* If the *statement* cannot syntactically be a *declaration*, there is no ambiguity, so this rule does not apply. The whole *statement* might need to be examined to determine whether this is the case. This resolves the meaning of many examples. [*Example:* Assuming `T` is a *simple-type-specifier* (7.519.1),

```
T(a)->m = 7;          // expression-statement
T(a)++;               // expression-statement
T(a,5)<<c;            // expression-statement

T(*d)(int);           // declaration
T(e)[5];              // declaration
T(f) = { 1, 2 };      // declaration
T(*g)(double(3));     // declaration
```

In the last example above, `g`, which is a pointer to `T`, is initialized to `double(3)`. This is of course ill-formed for semantic reasons, but that does not affect the syntactic analysis. — *end example*]

The remaining cases are *declaration*s. [*Example:*

```
class T {
  // ...
public:
  T();
  T(int);
  T(int, int);
};
T(a);                 // declaration
T(*b)();              // declaration
T(c)=7;               // declaration
T(d),e,f=3;           // declaration
extern int h;
T(g)(h,2);            // declaration
```

— *end example*] — *end note*]

1

The disambiguation is purely syntactic; that is, the meaning of the names occurring in such a statement, beyond whether they are *type-name*s or not, is not generally used in or changed by the disambiguation. Class templates are instantiated as necessary to determine if a qualified name is a *type-name*. Disambiguation precedes parsing, and a statement disambiguated as a declaration may be an ill-formed declaration. If, during parsing, a name in a template parameter is bound differently than it would be bound during a trial parse, the program is ill-formed. No diagnostic is required. [*Note:* This can occur only when the name is declared earlier in the declaration. — *end note*] [*Example:*

```
struct T1 {
  T1 operator()(int x) { return T1(x); }
  int operator=(int x) { return x; }
  T1(int) { }
};
struct T2 { T2(int){ } };
int a, (*(*b)(T2))(int), c, d;

void f() {
  // disambiguation requires this to be parsed as a declaration:
  T1(a) = 3,
  T2(4),                        // T2 will be declared as
  (*(*b)(T2(c)))(int(d));       // a variable of type T1
                                // but this will not allow
                                // the last part of the
                                // declaration to parse
                                // properly since it depends
                                // on T2 being a type-name
}
```

— *end example*]

7 Declarations [dcl.dcl]

1 Declarations generally specify how names are to be interpreted. Declarations have the form

declaration-seq:
  declaration
  declaration-seq declaration

declaration:
  block-declaration
  function-definition
  template-declaration
  explicit-instantiation
  explicit-specialization
  linkage-specification
  namespace-definition
  empty-declaration
  attribute-declaration

block-declaration:
  simple-declaration
  asm-definition
  namespace-alias-definition
  using-declaration
  using-directive
  static_assert-declaration
  alias-declaration
  opaque-enum-declaration

alias-declaration:
  `using` *identifier attribute-specifier-seq*$_{opt}$ `=` *type-id* `;`

simple-declaration:
  decl-specifier-seq$_{opt}$ *init-declarator-list*$_{opt}$ `;`
  attribute-specifier-seq decl-specifier-seq$_{opt}$ *init-declarator-list* `;`

static_assert-declaration:
  `static_assert (` *constant-expression* `,` *string-literal* `) ;`

empty-declaration:
  `;`

attribute-declaration:
  attribute-specifier-seq `;`

[*Note: asm-definition*s are described in 7.1473, and *linkage-specification*s are described in 7.1477. *Function-definition*s are described in 8.706 and *template-declaration*s are described in Clause 14. *Namespace-definition*s are described in 7.1149.1, *using-declaration*s are described in 7.1311.1 and *using-directive*s are described in 7.1416.1. — *end note*]

2 The *simple-declaration*

attribute-specifier-seq$_{opt}$ *decl-specifier-seq*$_{opt}$ *init-declarator-list*$_{opt}$ `;`

is divided into three parts. Attributes are described in 7.1546. *decl-specifier*s, the principal components of a *decl-specifier-seq*, are described in 7.40. *declarator*s, the components of an *init-declarator-list*, are described in Clause 8. The *attribute-specifier-seq* in a *simple-declaration* appertains to each of the entities declared by the *declarator*s of the *init-declarator-list*. [*Note:* In the declaration for an entity, attributes appertaining to that entity may appear at the start of the declaration and after the *declarator-id* for that declaration.

— *end note*] [*Example:*

```
[[noreturn]] void f [[noreturn]] (); // OK
```

— *end example*]

3 Except where otherwise specified, the meaning of an *attribute-declaration* is implementation-defined.

4 A declaration occurs in a scope (3.464); the scope rules are summarized in 3.923. A declaration that declares a function or defines a class, namespace, template, or function also has one or more scopes nested within it. These nested scopes, in turn, can have declarations nested within them. Unless otherwise stated, utterances in Clause 7 about components in, of, or contained by a declaration or subcomponent thereof refer only to those components of the declaration that are *not* nested within scopes nested within the declaration.

5

In a *simple-declaration*, the optional *init-declarator-list* can be omitted only when declaring a class (Clause 9) or enumeration (7.1001), that is, when the *decl-specifier-seq* contains either a *class-specifier*, an *elaborated-type-specifier* with a *class-key* (9.172), or an *enum-specifier*. In these cases and whenever a *class-specifier* or *enum-specifier* is present in the *decl-specifier-seq*, the identifiers in these specifiers are among the names being declared by the declaration (as *class-name*s, *enum-name*s, or *enumerator*s, depending on the syntax). In such cases, the *decl-specifier-seq* shall introduce one or more names into the program, or shall redeclare a name introduced by a previous declaration. [*Example:*

```
enum { };           // ill-formed
typedef class { };  // ill-formed
```

— *end example*]

1

In a *static_assert-declaration* the *constant-expression* shall be a constant expression (5.3643) that can be contextually converted to `bool` (Clause 4). If the value of the expression when so converted is `true`, the declaration has no effect. Otherwise, the program is ill-formed, and the resulting diagnostic message (1.196) shall include the text of the *string-literal*, except that characters not in the basic source character set (2.154) are not required to appear in the diagnostic message. [*Example:*

```
static_assert(sizeof(long) >= 8, "64-bit code generation required for this library.");
```

— *end example*]

1 An *empty-declaration* has no effect.

2

Each *init-declarator* in the *init-declarator-list* contains exactly one *declarator-id*, which is the name declared by that *init-declarator* and hence one of the names declared by the declaration. The *type-specifiers* (7.519.1) in the *decl-specifier-seq* and the recursive *declarator* structure of the *init-declarator* describe a type (8.56), which is then associated with the name being declared by the *init-declarator*.

1

If the *decl-specifier-seq* contains the `typedef` specifier, the declaration is called a *typedef declaration* and the name of each *init-declarator* is declared to be a *typedef-name*, synonymous with its associated type (7.235.1). If the *decl-specifier-seq* contains no `typedef` specifier, the declaration is called a *function declaration* if the type associated with the name is a function type (8.360.1) and an *object declaration* otherwise.

1

Syntactic components beyond those found in the general form of declaration are added to a function declaration to make a *function-definition*. An object declaration, however, is also a definition unless it contains

the `extern` specifier and has no initializer (3.43). A definition causes the appropriate amount of storage to be reserved and any appropriate initialization (8.821) to be done.

1

Only in function declarations for constructors, destructors, and type conversions can the *decl-specifier-seq* be omitted.[92]

7.40 Specifiers [dcl.spec]

1

The specifiers that can be used in a declaration are

decl-specifier:
- *storage-class-specifier*
- *type-specifier*
- *function-specifier*
- `friend`
- `typedef`
- `constexpr`

decl-specifier-seq:
- *decl-specifier attribute-specifier-seq*$_{opt}$
- *decl-specifier decl-specifier-seq*

The optional *attribute-specifier-seq* in a *decl-specifier-seq* appertains to the type determined by the preceding *decl-specifier*s (8.56). The *attribute-specifier-seq* affects the type only for the declaration it appears in, not other declarations involving the same type.

1

If a *type-name* is encountered while parsing a *decl-specifier-seq*, it is interpreted as part of the *decl-specifier-seq* if and only if there is no previous *type-specifier* other than a *cv-qualifier* in the *decl-specifier-seq*. The sequence shall be self-consistent as described below. [*Example:*

```
typedef char* Pc;
static Pc;                      // error: name missing
```

Here, the declaration `static Pc` is ill-formed because no name was specified for the static variable of type `Pc`. To get a variable called `Pc`, a *type-specifier* (other than `const` or `volatile`) has to be present to indicate that the *typedef-name* `Pc` is the name being (re)declared, rather than being part of the *decl-specifier* sequence. For another example,

```
void f(const Pc);               // void f(char* const) (not const char*)
void g(const int Pc);           // void g(const int)
```

— *end example*]

1

[*Note:* Since `signed`, `unsigned`, `long`, and `short` by default imply `int`, a *type-name* appearing after one of those specifiers is treated as the name being (re)declared. [*Example:*

```
void h(unsigned Pc);            // void h(unsigned int)
void k(unsigned int Pc);        // void k(unsigned int)
```

— *end example*] — *end note*]

92) The "implicit int" rule of C is no longer supported.

7.49.1 Storage class specifiers [dcl.stc]

1

The storage class specifiers are

storage-class-specifier:
`register`
`static`
`thread_local`
`extern`
`mutable`

At most one *storage-class-specifier* shall appear in a given *decl-specifier-seq*, except that `thread_local` may appear with `static` or `extern`. If `thread_local` appears in any declaration of a variable it shall be present in all declarations of that entity. If a *storage-class-specifier* appears in a *decl-specifier-seq*, there can be no `typedef` specifier in the same *decl-specifier-seq* and the *init-declarator-list* of the declaration shall not be empty (except for an anonymous union declared in a named namespace or in the global namespace, which shall be declared `static` (9.815)). The *storage-class-specifier* applies to the name declared by each *init-declarator* in the list and not to any names declared by other specifiers. A *storage-class-specifier* shall not be specified in an explicit specialization (14.1921.1) or an explicit instantiation (14.1841.1) directive.

1

The `register` specifier shall be applied only to names of variables declared in a block (6.15) or to function parameters (8.706). It specifies that the named variable has automatic storage duration (3.2301.1). A variable declared without a *storage-class-specifier* at block scope or declared as a function parameter has automatic storage duration by default.

1

A `register` specifier is a hint to the implementation that the variable so declared will be heavily used. [*Note:* The hint can be ignored and in most implementations it will be ignored if the address of the variable is taken. This use is deprecated (see D.4). — *end note*]

1

The `thread_local` specifier indicates that the named entity has thread storage duration (3.2291.1). It shall be applied only to the names of variables of namespace or block scope and to the names of static data members. When `thread_local` is applied to a variable of block scope the *storage-class-specifier* `static` is implied if no other *storage-class-specifier* appears in the *decl-specifier-seq*.

1

The `static` specifier can be applied only to names of variables and functions and to anonymous unions (9.815). There can be no `static` function declarations within a block, nor any `static` function parameters. A `static` specifier used in the declaration of a variable declares the variable to have static storage duration (3.2242.1), unless accompanied by the `thread_local` specifier, which declares the variable to have thread storage duration (3.2291.1). A `static` specifier can be used in declarations of class members; 9.559 describes its effect. For the linkage of a name declared with a `static` specifier, see 3.1459.

1

The `extern` specifier can be applied only to the names of variables and functions. The `extern` specifier cannot be used in the declaration of class members or function parameters. For the linkage of a name declared with an `extern` specifier, see 3.1459. [*Note:* The `extern` keyword can also be used in *explicit-instantiation*s and *linkage-specification*s, but it is not a *storage-class-specifier* in such contexts. — *end note*]

1

The linkages implied by successive declarations for a given entity shall agree. That is, within a given scope, each declaration declaring the same variable name or the same overloading of a function name shall imply

the same linkage. Each function in a given set of overloaded functions can have a different linkage, however. [*Example:*

```
static char* f();                // f() has internal linkage
char* f()                        // f() still has internal linkage
  { /* ... */ }

char* g();                       // g() has external linkage
static char* g()                 // error: inconsistent linkage
  { /* ... */ }

void h();
inline void h();                 // external linkage

inline void l();
void l();                        // external linkage

inline void m();
extern void m();                 // external linkage

static void n();
inline void n();                 // internal linkage

static int a;                    // a has internal linkage
int a;                           // error: two definitions

static int b;                    // b has internal linkage
extern int b;                    // b still has internal linkage

int c;                           // c has external linkage
static int c;                    // error: inconsistent linkage

extern int d;                    // d has external linkage
static int d;                    // error: inconsistent linkage
```

— *end example*]

1

The name of a declared but undefined class can be used in an `extern` declaration. Such a declaration can only be used in ways that do not require a complete class type. [*Example:*

```
struct S;
extern S a;
extern S f();
extern void g(S);

void h() {
  g(a);                          // error: S is incomplete
  f();                           // error: S is incomplete
}
```

— *end example*]

1

The `mutable` specifier can be applied only to names of class data members (9.194) and cannot be applied to names declared `const` or `static`, and cannot be applied to reference members. [*Example:*

```
class X {
  mutable const int* p;          // OK
  mutable int* const q;          // ill-formed
};
```

— *end example*]

1

The `mutable` specifier on a class data member nullifies a `const` specifier applied to the containing class object and permits modification of the mutable class member even though the rest of the object is `const` (7.567.0.1).

7.94.1 Function specifiers [dcl.fct.spec]

1

Function-specifiers can be used only in function declarations.

function-specifier:
`inline`
`virtual`
`explicit`

1

A function declaration (8.360.1, 9.401, 11.94) with an `inline` specifier declares an *inline function*. The inline specifier indicates to the implementation that inline substitution of the function body at the point of call is to be preferred to the usual function call mechanism. An implementation is not required to perform this inline substitution at the point of call; however, even if this inline substitution is omitted, the other rules for inline functions defined by 7.94.1 shall still be respected.

1

A function defined within a class definition is an inline function. The `inline` specifier shall not appear on a block scope function declaration.[93] If the `inline` specifier is used in a friend declaration, that declaration shall be a definition or the function shall have previously been declared inline.

1

An inline function shall be defined in every translation unit in which it is odr-used and shall have exactly the same definition in every case (3.91). [*Note:* A call to the inline function may be encountered before its definition appears in the translation unit. — *end note*] If the definition of a function appears in a translation unit before its first declaration as inline, the program is ill-formed. If a function with external linkage is declared inline in one translation unit, it shall be declared inline in all translation units in which it appears; no diagnostic is required. An `inline` function with external linkage shall have the same address in all translation units. A `static` local variable in an `extern inline` function always refers to the same object. A string literal in the body of an `extern inline` function is the same object in different translation units. [*Note:* A string literal appearing in a default argument is not in the body of an inline function merely because the expression is used in a function call from that inline function. — *end note*] A type defined within the body of an `extern inline` function is the same type in every translation unit.

1

The `virtual` specifier shall be used only in the initial declaration of a non-static class member function; see 10.113.

1

The `explicit` specifier shall be used only in the declaration of a constructor or conversion function within its class definition; see 12.708.1 and 12.742.1.

93) The inline keyword has no effect on the linkage of a function.

7.235.1 The `typedef` specifier [dcl.typedef]

1

Declarations containing the *decl-specifier* `typedef` declare identifiers that can be used later for naming fundamental (3.3151.1) or compound (3.3568.1) types. The `typedef` specifier shall not be combined in a *decl-specifier-seq* with any other kind of specifier except a *type-specifier,* and it shall not be used in the *decl-specifier-seq* of a *parameter-declaration* (8.360.1) nor in the *decl-specifier-seq* of a *function-definition* (8.706).

typedef-name:
identifier

A name declared with the `typedef` specifier becomes a *typedef-name*. Within the scope of its declaration, a *typedef-name* is syntactically equivalent to a keyword and names the type associated with the identifier in the way described in Clause 8. A *typedef-name* is thus a synonym for another type. A *typedef-name* does not introduce a new type the way a class declaration (9.172) or enum declaration does. [*Example:* after

```
typedef int MILES, *KLICKSP;
```

the constructions

```
MILES distance;
extern KLICKSP metricp;
```

are all correct declarations; the type of `distance` is `int` and that of `metricp` is "pointer to `int`." — *end example*]

1

A *typedef-name* can also be introduced by an *alias-declaration*. The *identifier* following the `using` keyword becomes a *typedef-name* and the optional *attribute-specifier-seq* following the *identifier* appertains to that *typedef-name*. It has the same semantics as if it were introduced by the `typedef` specifier. In particular, it does not define a new type and it shall not appear in the *type-id*. [*Example:*

```
using handler_t = void (*)(int);
extern handler_t ignore;
extern void (*ignore)(int);          // redeclare ignore
using cell = pair<void*, cell*>;     // ill-formed
```

— *end example*]

1

In a given non-class scope, a `typedef` specifier can be used to redefine the name of any type declared in that scope to refer to the type to which it already refers. [*Example:*

```
typedef struct s { /* ... */ } s;
typedef int I;
typedef int I;
typedef I I;
```

— *end example*]

1 In a given class scope, a `typedef` specifier can be used to redefine any *class-name* declared in that scope that is not also a *typedef-name* to refer to the type to which it already refers. [*Example:*

```
struct S {
  typedef struct A { } A;        // OK
  typedef struct B B;            // OK
  typedef A A;                   // error
};
```

— *end example*]

2

If a `typedef` specifier is used to redefine in a given scope an entity that can be referenced using an *elaborated-type-specifier*, the entity can continue to be referenced by an *elaborated-type-specifier* or as an enumeration or class name in an enumeration or class definition respectively. [*Example:*

```
struct S;
typedef struct S S;
int main() {
  struct S* p;                  // OK
}
struct S { };                   // OK
```

— *end example*]

1

In a given scope, a `typedef` specifier shall not be used to redefine the name of any type declared in that scope to refer to a different type. [*Example:*

```
class complex { /* ... */ };
typedef int complex;            // error: redefinition
```

— *end example*]

1

Similarly, in a given scope, a class or enumeration shall not be declared with the same name as a *typedef-name* that is declared in that scope and refers to a type other than the class or enumeration itself. [*Example:*

```
typedef int complex;
class complex { /* ...  */ };   // error: redefinition
```

— *end example*]

1

[*Note:* A *typedef-name* that names a class type, or a cv-qualified version thereof, is also a *class-name* (9.172). If a *typedef-name* is used to identify the subject of an *elaborated-type-specifier* (7.808.0.1), a class definition (Clause 9), a constructor declaration (12.30), or a destructor declaration (12.807), the program is ill-formed. — *end note*] [*Example:*

```
struct S {
  S();
  ~S();
};

typedef struct S T;

S a = T();                      // OK
struct T * p;                   // error
```

— *end example*]

1

If the typedef declaration defines an unnamed class (or enum), the first *typedef-name* declared by the declaration to be that class type (or enum type) is used to denote the class type (or enum type) for linkage purposes only (3.1459). [*Example:*

```
typedef struct { } *ps, S;      // S is the class name for linkage purposes
```

— *end example*]

7.327.1 The `friend` specifier [dcl.friend]

1

The `friend` specifier is used to specify access to class members; see 11.94.

7.328.1 The `constexpr` specifier [dcl.constexpr]

1

The `constexpr` specifier shall be applied only to the definition of a variable or variable template, the declaration of a function or function template, or the declaration of a static data member of a literal type (3.2955). If any declaration of a function, function template, or variable template has a `constexpr` specifier, then all its declarations shall contain the `constexpr` specifier. [*Note:* An explicit specialization can differ from the template declaration with respect to the `constexpr` specifier. — *end note*] [*Note:* Function parameters cannot be declared `constexpr`. — *end note*] [*Example:*

```
constexpr void square(int &x);  // OK: declaration
constexpr int bufsz = 1024;     // OK: definition
constexpr struct pixel {        // error: pixel is a type
  int x;
  int y;
  constexpr pixel(int);         // OK: declaration
};
constexpr pixel::pixel(int a)
  : x(a), y(x)                  // OK: definition
  { square(x); }
constexpr pixel small(2);       // error: square not defined, so small(2)
                                // not constant (5.3643) so constexpr not satisfied

constexpr void square(int &x) { // OK: definition
  x *= x;
}
constexpr pixel large(4);       // OK: square defined
int next(constexpr int x) {     // error: not for parameters
     return x + 1;
}
extern constexpr int memsz;     // error: not a definition
```

— *end example*]

1

A `constexpr` specifier used in the declaration of a function that is not a constructor declares that function to be a *constexpr function*. Similarly, a `constexpr` specifier used in a constructor declaration declares that constructor to be a *constexpr constructor*. `constexpr` functions and `constexpr` constructors are implicitly `inline` (7.94.1).

1

The definition of a `constexpr` function shall satisfy the following constraints:

— it shall not be virtual (10.113);

— its return type shall be a literal type;

— each of its parameter types shall be a literal type;

— its *function-body* shall be `= delete`, `= default`, or a *compound-statement* that does not contain
  — an *asm-definition*,
  — a `goto` statement,
  — a *try-block*, or
  — a definition of a variable of non-literal type or of static or thread storage duration or for which no initialization is performed.

[*Example:*

```
constexpr int square(int x)
  { return x * x; }             // OK
constexpr long long_max()
  { return 2147483647; }        // OK
constexpr int abs(int x) {
  if (x < 0)
    x = -x;
  return x;                     // OK
}
constexpr int first(int n) {
  static int value = n;         // error: variable has static storage duration
  return value;
}
constexpr int uninit() {
  int a;                        // error: variable is uninitialized
  return a;
}
constexpr int prev(int x)
  { return --x; }               // OK
constexpr int g(int x, int n) { // OK
  int r = 1;
  while (--n > 0) r *= x;
  return r;
}
```

— *end example*]

1

The definition of a `constexpr` constructor shall satisfy the following constraints:

— the class shall not have any virtual base classes;

— each of the parameter types shall be a literal type;

— its *function-body* shall not be a *function-try-block*;

In addition, either its *function-body* shall be `= delete`, or it shall satisfy the following constraints:

— either its *function-body* shall be `= default`, or the *compound-statement* of its *function-body* shall satisfy the constraints for a *function-body* of a `constexpr` function;

— every non-variant non-static data member and base class sub-object shall be initialized (12.1026.1);

— if the class is a union having variant members (9.815), exactly one of them shall be initialized;

— if the class is a union-like class, but is not a union, for each of its anonymous union members having variant members, exactly one of them shall be initialized;

— for a non-delegating constructor, every constructor selected to initialize non-static data members and base class sub-objects shall be a `constexpr` constructor;

— for a delegating constructor, the target constructor shall be a `constexpr` constructor.

[*Example:*

```
struct Length {
  constexpr explicit Length(int i = 0) : val(i) { }
private:
  int val;
};
```

— *end example*]

1

For a non-template, non-defaulted `constexpr` function or a non-template, non-defaulted, non-inheriting `constexpr` constructor, if no argument values exist such that an invocation of the function or constructor could be an evaluated subexpression of a core constant expression (5.3643), the program is ill-formed; no diagnostic required. [*Example:*

```
constexpr int f(bool b)
  { return b ? throw 0 : 0; }              // OK
constexpr int f() { return f(true); }      // ill-formed, no diagnostic required

struct B {
  constexpr B(int x) : i(0) { }            // x is unused
  int i;
};

int global;

struct D : B {
  constexpr D() : B(global) { }            // ill-formed, no diagnostic required
                                           // lvalue-to-rvalue conversion on non-constant global
};
```

— *end example*]

1

If the instantiated template specialization of a `constexpr` function template or member function of a class template would fail to satisfy the requirements for a `constexpr` function or `constexpr` constructor, that specialization is still a `constexpr` function or `constexpr` constructor, even though a call to such a function cannot appear in a constant expression. If no specialization of the template would satisfy the requirements for a `constexpr` function or `constexpr` constructor when considered as a non-template function or constructor, the template is ill-formed; no diagnostic required.

1

A call to a `constexpr` function produces the same result as a call to an equivalent non-`constexpr` function in all respects except that a call to a `constexpr` function can appear in a constant expression.

1

The `constexpr` specifier has no effect on the type of a `constexpr` function or a `constexpr` constructor. [*Example:*

```
constexpr int bar(int x, int y) // OK
    { return x + y + x*y; }
// ...
int bar(int x, int y)           // error: redefinition of bar
    { return x * 2 + 3 * y; }
```

— *end example*]

1

A `constexpr` specifier used in an object declaration declares the object as `const`. Such an object shall have literal type and shall be initialized. If it is initialized by a constructor call, that call shall be a constant expression (5.3643). Otherwise, or if a `constexpr` specifier is used in a reference declaration, every full-expression that appears in its initializer shall be a constant expression. [*Note:* Each implicit conversion used in converting the initializer expressions and each constructor call used for the initialization is part of such a full-expression. — *end note*] [*Example:*

```
struct pixel {
  int x, y;
};
constexpr pixel ur = { 1294, 1024 };// OK
constexpr pixel origin;             // error: initializer missing
```

— *end example*]

7.519.1 Type specifiers [dcl.type]

1 The type-specifiers are

type-specifier:
  trailing-type-specifier
  class-specifier
  enum-specifier

trailing-type-specifier:
  simple-type-specifier
  elaborated-type-specifier
  typename-specifier
  cv-qualifier

type-specifier-seq:
  type-specifier attribute-specifier-seq$_{opt}$
  type-specifier type-specifier-seq

trailing-type-specifier-seq:
  trailing-type-specifier attribute-specifier-seq$_{opt}$
  trailing-type-specifier trailing-type-specifier-seq

The optional *attribute-specifier-seq* in a *type-specifier-seq* or a *trailing-type-specifier-seq* appertains to the type denoted by the preceding *type-specifier*s (8.56). The *attribute-specifier-seq* affects the type only for the declaration it appears in, not other declarations involving the same type.

2

As a general rule, at most one *type-specifier* is allowed in the complete *decl-specifier-seq* of a *declaration* or in a *type-specifier-seq* or *trailing-type-specifier-seq*. The only exceptions to this rule are the following:

— `const` can be combined with any type specifier except itself.

— `volatile` can be combined with any type specifier except itself.

— `signed` or `unsigned` can be combined with `char`, `long`, `short`, or `int`.

— `short` or `long` can be combined with `int`.

— `long` can be combined with `double`.

— `long` can be combined with `long`.

1

Except in a declaration of a constructor, destructor, or conversion function, at least one *type-specifier* that is not a *cv-qualifier* shall appear in a complete *type-specifier-seq* or a complete *decl-specifier-seq*.[94] A *type-specifier-seq* shall not define a class or enumeration unless it appears in the *type-id* of an *alias-declaration* (7.235.1) that is not the *declaration* of a *template-declaration*.

1 [*Note:* *enum-specifier*s, *class-specifier*s, and *typename-specifier*s are discussed in 7.1001, Clause 9, and 14.1061, respectively. The remaining *type-specifier*s are discussed in the rest of this section. — *end note*]

7.567.0.1 The *cv-qualifiers* [dcl.type.cv]

1

There are two *cv-qualifiers*, `const` and `volatile`. Each *cv-qualifier* shall appear at most once in a *cv-qualifier-seq*. If a *cv-qualifier* appears in a *decl-specifier-seq*, the *init-declarator-list* of the declaration shall not be empty. [*Note:* 3.3640.1 and 8.360.1 describe how cv-qualifiers affect object and function types. — *end note*] Redundant cv-qualifications are ignored. [*Note:* For example, these could be introduced by typedefs. — *end note*]

1

[*Note:* Declaring a variable `const` can affect its linkage (7.49.1) and its usability in constant expressions (5.3643). As described in 8.821, the definition of an object or subobject of const-qualified type must specify an initializer or be subject to default-initialization. — *end note*]

1

A pointer or reference to a cv-qualified type need not actually point or refer to a cv-qualified object, but it is treated as if it does; a const-qualified access path cannot be used to modify an object even if the object referenced is a non-const object and can be modified through some other access path. [*Note:* Cv-qualifiers are supported by the type system so that they cannot be subverted without casting (5.1871.1). — *end note*]

1

Except that any class member declared `mutable` (7.49.1) can be modified, any attempt to modify a `const` object during its lifetime (3.2563) results in undefined behavior. [*Example:*

```
const int ci = 3;               // cv-qualified (initialized as required)
ci = 4;                         // ill-formed: attempt to modify const

int i = 2;                      // not cv-qualified
const int* cip;                 // pointer to const int
cip = &i;                       // OK: cv-qualified access path to unqualified
*cip = 4;                       // ill-formed: attempt to modify through ptr to const

int* ip;
ip = const_cast<int*>(cip);     // cast needed to convert const int* to int*
*ip = 4;                        // defined: *ip points to i, a non-const object

const int* ciq = new const int (3);     // initialized as required
int* iq = const_cast<int*>(ciq);        // cast required
```

94) There is no special provision for a *decl-specifier-seq* that lacks a *type-specifier* or that has a *type-specifier* that only specifies *cv-qualifier*s. The "implicit int" rule of C is no longer supported.

```
*iq = 4;                                // undefined: modifies a const object
```

1 For another example

```
struct X {
  mutable int i;
  int j;
};
struct Y {
  X x;
  Y();
};

const Y y;
y.x.i++;                        // well-formed: mutable member can be modified
y.x.j++;                        // ill-formed: const-qualified member modified
Y* p = const_cast<Y*>(&y);      // cast away const-ness of y
p->x.i = 99;                    // well-formed: mutable member can be modified
p->x.j = 99;                    // undefined: modifies a const member
```

— *end example*]

2

What constitutes an access to an object that has volatile-qualified type is implementation-defined. If an attempt is made to refer to an object defined with a volatile-qualified type through the use of a glvalue with a non-volatile-qualified type, the program behavior is undefined.

1

[*Note:* `volatile` is a hint to the implementation to avoid aggressive optimization involving the object because the value of the object might be changed by means undetectable by an implementation. Furthermore, for some implementations, `volatile` might indicate that special hardware instructions are required to access the object. See 1.430 for detailed semantics. In general, the semantics of `volatile` are intended to be the same in C++ as they are in C. — *end note*]

7.678.0.1 Simple type specifiers [dcl.type.simple]

1

The simple type specifiers are

simple-type-specifier:
- *nested-name-specifier*$_{opt}$ *type-name*
- *nested-name-specifier* `template` *simple-template-id*
- `char`
- `char16_t`
- `char32_t`
- `wchar_t`
- `bool`
- `short`
- `int`
- `long`
- `signed`
- `unsigned`
- `float`
- `double`
- `void`
- `auto`
- *decltype-specifier*

type-name:
  class-name
  enum-name
  typedef-name
  simple-template-id

decltype-specifier:
  `decltype` (*expression*)
  `decltype ( auto )`

1

The `auto` specifier is a placeholder for a type to be deduced (7.832.0.1). The other *simple-type-specifier*s specify either a previously-declared type, a type determined from an expression, or one of the fundamental types (3.3151.1). Table 10 summarizes the valid combinations of *simple-type-specifier*s and the types they specify.

1

When multiple *simple-type-specifiers* are allowed, they can be freely intermixed with other *decl-specifiers* in any order. [*Note:* It is implementation-defined whether objects of `char` type are represented as signed or unsigned quantities. The `signed` specifier forces `char` objects to be signed; it is redundant in other contexts. — *end note*]

Table 10 — *simple-type-specifier*s and the types they specify

Specifier(s)	Type
type-name	the type named
simple-template-id	the type as defined in 14.224
char	"char"
unsigned char	"unsigned char"
signed char	"signed char"
char16_t	"char16_t"
char32_t	"char32_t"
bool	"bool"
unsigned	"unsigned int"
unsigned int	"unsigned int"
signed	"int"
signed int	"int"
int	"int"
unsigned short int	"unsigned short int"
unsigned short	"unsigned short int"
unsigned long int	"unsigned long int"
unsigned long	"unsigned long int"
unsigned long long int	"unsigned long long int"
unsigned long long	"unsigned long long int"
signed long int	"long int"
signed long	"long int"
signed long long int	"long long int"
signed long long	"long long int"
long long int	"long long int"
long long	"long long int"
long int	"long int"
long	"long int"
signed short int	"short int"
signed short	"short int"
short int	"short int"
short	"short int"
wchar_t	"wchar_t"
float	"float"
double	"double"
long double	"long double"
void	"void"
auto	placeholder for a type to be deduced
decltype(*expression*)	the type as defined below

1

For an expression `e`, the type denoted by `decltype(e)` is defined as follows:

— if `e` is an unparenthesized *id-expression* or an unparenthesized class member access (5.1194.1), `decltype(e)` is the type of the entity named by `e`. If there is no such entity, or if `e` names a set of overloaded functions, the program is ill-formed;

— otherwise, if `e` is an xvalue, `decltype(e)` is `T&&`, where `T` is the type of `e`;

— otherwise, if `e` is an lvalue, `decltype(e)` is `T&`, where `T` is the type of `e`;

— otherwise, `decltype(e)` is the type of `e`.

The operand of the `decltype` specifier is an unevaluated operand (Clause 5).

[*Example:*

```
const int&& foo();
int i;
struct A { double x; };
const A* a = new A();
decltype(foo()) x1 = 0;          // type is const int&&
decltype(i) x2;                  // type is int
decltype(a->x) x3;               // type is double
decltype((a->x)) x4 = x3;        // type is const double&
```

— *end example*] [*Note:* The rules for determining types involving `decltype(auto)` are specified in 7.832.0.1. — *end note*]

1 [*Note:* in the case where the operand of a *decltype-specifier* is a function call and the return type of the function is a class type, a special rule (5.955.1) ensures that the return type is not required to be complete (as it would be if the call appeared in a sub-expression or outside of a *decltype-specifier*). In this context, the common purpose of writing the expression is merely to refer to its type. In that sense, a *decltype-specifier* is analogous to a use of a *typedef-name*, so the usual reasons for requiring a complete type do not apply. In particular, it is not necessary to allocate storage for a temporary object or to enforce the semantic constraints associated with invoking the type's destructor. [*Example:*

```
template<class T> struct A { ~A() = delete; };
template<class T> auto h()
  -> A<T>;
template<class T> auto i(T)      // identity
  -> T;
template<class T> auto f(T)      // #1
  -> decltype(i(h<T>()));        // forces completion of A<T> and implicitly uses
                                 // A<T>::~A() for the temporary introduced by the
                                 // use of h(). (A temporary is not introduced
                                 // as a result of the use of i().)
template<class T> auto f(T)      // #2
  -> void;
auto g() -> void {
  f(42);                         // OK: calls #2. (#1 is not a viable candidate: type
                                 // deduction fails (14.2114.1) because A<int>::~A()
                                 // is implicitly used in its decltype-specifier)
}
template<class T> auto q(T)
  -> decltype((h<T>()));         // does not force completion of A<T>; A<T>::~A() is
```

```
                                  // not implicitly used within the context of this decltype-specifier
void r() {
  q(42);                          // Error: deduction against q succeeds, so overload resolution
                                  // selects the specialization "q(T) -> decltype((h<T>())) [with T=int]".
                                  // The return type is A<int>, so a temporary is introduced and its
                                  // destructor is used, so the program is ill-formed.
}
```

— *end example*] — *end note*]

7.808.0.1 Elaborated type specifiers [dcl.type.elab]

elaborated-type-specifier:
class-key attribute-specifier-seq$_{opt}$ *nested-name-specifier*$_{opt}$ *identifier*
class-key simple-template-id
class-key nested-name-specifier `template`$_{opt}$ *simple-template-id*
`enum` *nested-name-specifier*$_{opt}$ *identifier*

1

An *attribute-specifier-seq* shall not appear in an *elaborated-type-specifier* unless the latter is the sole constituent of a declaration. If an *elaborated-type-specifier* is the sole constituent of a declaration, the declaration is ill-formed unless it is an explicit specialization (14.1921.1), an explicit instantiation (14.1841.1) or it has one of the following forms:

class-key attribute-specifier-seq$_{opt}$ *identifier* `;`
`friend` *class-key* `::`$_{opt}$ *identifier* `;`
`friend` *class-key* `::`$_{opt}$ *simple-template-id* `;`
`friend` *class-key nested-name-specifier identifier* `;`
`friend` *class-key nested-name-specifier* `template`$_{opt}$ *simple-template-id* `;`

In the first case, the *attribute-specifier-seq*, if any, appertains to the class being declared; the attributes in the *attribute-specifier-seq* are thereafter considered attributes of the class whenever it is named.

1

3.1395.1 describes how name lookup proceeds for the *identifier* in an *elaborated-type-specifier*. If the *identifier* resolves to a *class-name* or *enum-name*, the *elaborated-type-specifier* introduces it into the declaration the same way a *simple-type-specifier* introduces its *type-name*. If the *identifier* resolves to a *typedef-name* or the *simple-template-id* resolves to an alias template specialization, the *elaborated-type-specifier* is ill-formed. [*Note:* This implies that, within a class template with a template *type-parameter* `T`, the declaration

```
friend class T;
```

is ill-formed. However, the similar declaration `friend T;` is allowed (11.94). — *end note*]

1

The *class-key* or `enum` keyword present in the *elaborated-type-specifier* shall agree in kind with the declaration to which the name in the *elaborated-type-specifier* refers. This rule also applies to the form of *elaborated-type-specifier* that declares a *class-name* or `friend` class since it can be construed as referring to the definition of the class. Thus, in any *elaborated-type-specifier*, the `enum` keyword shall be used to refer to an enumeration (7.1001), the `union` *class-key* shall be used to refer to a union (Clause 9), and either the `class` or `struct` *class-key* shall be used to refer to a class (Clause 9) declared using the `class` or `struct` *class-key*. [*Example:*

```
enum class E { a, b };
enum E x = E::a;                  // OK
```

— *end example*]

7.832.0.1 `auto` specifier [dcl.spec.auto]

1

The `auto` and `decltype(auto)` *type-specifier*s designate a placeholder type that will be replaced later, either by deduction from an initializer or by explicit specification with a *trailing-return-type*. The `auto` *type-specifier* is also used to signify that a lambda is a generic lambda.

1

The placeholder type can appear with a function declarator in the *decl-specifier-seq*, *type-specifier-seq*, *conversion-function-id*, or *trailing-return-type*, in any context where such a declarator is valid. If the function declarator includes a *trailing-return-type* (8.360.1), that specifies the declared return type of the function. If the declared return type of the function contains a placeholder type, the return type of the function is deduced from `return` statements in the body of the function, if any.

1

If the `auto` *type-specifier* appears as one of the *decl-specifier*s in the *decl-specifier-seq* of a *parameter-declaration* of a *lambda-expression*, the lambda is a *generic lambda* (5.509.1). [*Example:*

```
auto glambda = [](int i, auto a) { return i; }; // OK: a generic lambda
```

— *end example*]

1

The type of a variable declared using `auto` or `decltype(auto)` is deduced from its initializer. This use is allowed when declaring variables in a block (6.15), in namespace scope (3.736.1), and in a *for-init-statement* (6.150.1). `auto` or `decltype(auto)` shall appear as one of the *decl-specifier*s in the *decl-specifier-seq* and the *decl-specifier-seq* shall be followed by one or more *init-declarator*s, each of which shall have a non-empty *initializer*. In an *initializer* of the form

```
( expression-list )
```

the *expression-list* shall be a single *assignment-expression*.

[*Example:*

```
auto x = 5;                  // OK: x has type int
const auto *v = &x, u = 6;   // OK: v has type const int*, u has type const int
static auto y = 0.0;         // OK: y has type double
auto int r;                  // error: auto is not a storage-class-specifier
auto f() -> int;             // OK: f returns int
auto g() { return 0.0; }     // OK: g returns double
auto h();                    // OK: h's return type will be deduced when it is defined
```

— *end example*]

1

A placeholder type can also be used in declaring a variable in the *condition* of a selection statement (6.23) or an iteration statement (6.137), in the *type-specifier-seq* in the *new-type-id* or *type-id* of a *new-expression* (5.2221.1), in a *for-range-declaration*, and in declaring a static data member with a *brace-or-equal-initializer* that appears within the *member-specification* of a class definition (9.595.1).

1

A program that uses `auto` or `decltype(auto)` in a context not explicitly allowed in this section is ill-formed.

1

When a variable declared using a placeholder type is initialized, or a `return` statement occurs in a function declared with a return type that contains a placeholder type, the deduced return type or variable type is de-

termined from the type of its initializer. In the case of a `return` with no operand, the initializer is considered to be `void()`. Let `T` be the declared type of the variable or return type of the function. If the placeholder is the `auto` *type-specifier*, the deduced type is determined using the rules for template argument deduction. If the deduction is for a `return` statement and the initializer is a *braced-init-list* (8.2435.1), the program is ill-formed. Otherwise, obtain `P` from `T` by replacing the occurrences of `auto` with either a new invented type template parameter `U` or, if the initializer is a *braced-init-list*, with `std::initializer_list<U>`. Deduce a value for `U` using the rules of template argument deduction from a function call (14.2261.0.1), where `P` is a function template parameter type and the initializer is the corresponding argument. If the deduction fails, the declaration is ill-formed. Otherwise, the type deduced for the variable or return type is obtained by substituting the deduced `U` into `P`. [*Example:*

```
auto x1 = { 1, 2 };          // decltype(x1) is std::initializer_list<int>
auto x2 = { 1, 2.0 };        // error: cannot deduce element type
```

— *end example*]

[*Example:*

```
const auto &i = expr;
```

The type of `i` is the deduced type of the parameter `u` in the call `f(expr)` of the following invented function template:

```
template <class U> void f(const U& u);
```

— *end example*]

If the placeholder is the `decltype(auto)` *type-specifier*, the declared type of the variable or return type of the function shall be the placeholder alone. The type deduced for the variable or return type is determined as described in 7.678.0.1, as though the initializer had been the operand of the `decltype`. [*Example:*

```
int i;
int&& f();
auto           x3a = i;        // decltype(x3a) is int
decltype(auto) x3d = i;        // decltype(x3d) is int
auto           x4a = (i);      // decltype(x4a) is int
decltype(auto) x4d = (i);      // decltype(x4d) is int&
auto           x5a = f();      // decltype(x5a) is int
decltype(auto) x5d = f();      // decltype(x5d) is int&&
auto           x6a = { 1, 2 }; // decltype(x6a) is std::initializer_list<int>
decltype(auto) x6d = { 1, 2 }; // error, { 1, 2 } is not an expression
auto          *x7a = &i;       // decltype(x7a) is int*
decltype(auto)*x7d = &i;       // error, declared type is not plain decltype(auto)
```

— *end example*]

1

If the *init-declarator-list* contains more than one *init-declarator*, they shall all form declarations of variables. The type of each declared variable is determined as described above, and if the type that replaces the placeholder type is not the same in each deduction, the program is ill-formed.

[*Example:*

```
auto x = 5, *y = &x;         // OK: auto is int
auto a = 5, b = { 1, 2 };    // error: different types for auto
```

— *end example*]

1

If a function with a declared return type that contains a placeholder type has multiple `return` statements, the return type is deduced for each `return` statement. If the type deduced is not the same in each deduction, the program is ill-formed.

1

If a function with a declared return type that uses a placeholder type has no `return` statements, the return type is deduced as though from a `return` statement with no operand at the closing brace of the function body. [*Example:*

```
auto  f() { } // OK, return type is void
auto* g() { } // error, cannot deduce auto* from void()
```

— *end example*]

1

If the type of an entity with an undeduced placeholder type is needed to determine the type of an expression, the program is ill-formed. Once a `return` statement has been seen in a function, however, the return type deduced from that statement can be used in the rest of the function, including in other `return` statements. [*Example:*

```
auto n = n;             // error, n's type is unknown
auto f();
void g() { &f; }        // error, f's return type is unknown
auto sum(int i) {
  if (i == 1)
    return i;           // sum's return type is int
  else
    return sum(i-1)+i;  // OK, sum's return type has been deduced
}
```

— *end example*]

1

Return type deduction for a function template with a placeholder in its declared type occurs when the definition is instantiated even if the function body contains a `return` statement with a non-type-dependent operand. [*Note:* Therefore, any use of a specialization of the function template will cause an implicit instantiation. Any errors that arise from this instantiation are not in the immediate context of the function type and can result in the program being ill-formed. — *end note*] [*Example:*

```
template <class T> auto f(T t) { return t; }  // return type deduced at instantiation time
typedef decltype(f(1)) fint_t;                // instantiates f<int> to deduce return type
template<class T> auto f(T* t) { return *t; }
void g() { int (*p)(int*) = &f; }             // instantiates both fs to determine return types,
                                              // chooses second
```

— *end example*]

1

Redeclarations or specializations of a function or function template with a declared return type that uses a placeholder type shall also use that placeholder, not a deduced type. [*Example:*

```
auto f();
auto f() { return 42; } // return type is int
auto f();               // OK
int f();                // error, cannot be overloaded with auto f()
decltype(auto) f();     // error, auto and decltype(auto) don't match
```

```
template <typename T> auto g(T t) { return t; } // #1
template auto g(int);                           // OK, return type is int
template char g(char);                          // error, no matching template
template<> auto g(double);                      // OK, forward declaration with unknown return type

template <class T> T g(T t) { return t; } // OK, not functionally equivalent to #1
template char g(char);                    // OK, now there is a matching template
template auto g(float);                   // still matches #1

void h() { return g(42); } // error, ambiguous

template <typename T> struct A {
  friend T frf(T);
};
auto frf(int i) { return i; } // not a friend of A<int>
```

— *end example*]

1

A function declared with a return type that uses a placeholder type shall not be `virtual` (10.113).

1 An explicit instantiation declaration (14.1841.1) does not cause the instantiation of an entity declared using a placeholder type, but it also does not prevent that entity from being instantiated as needed to determine its type. [*Example:*

```
template <typename T> auto f(T t) { return t; }
extern template auto f(int); // does not instantiate f<int>
int (*p)(int) = f;           // instantiates f<int> to determine its return type, but an explicit
                             // instantiation definition is still required somewhere in the program
```

— *end example*]

7.1001 Enumeration declarations [dcl.enum]

1

An enumeration is a distinct type (3.3568.1) with named constants. Its name becomes an *enum-name*, within its scope.

enum-name:
  identifier

enum-specifier:
  enum-head `{` *enumerator-list*$_{opt}$`}`
  enum-head `{` *enumerator-list* `,` `}`

enum-head:
  enum-key attribute-specifier-seq$_{opt}$ *identifier*$_{opt}$ *enum-base*$_{opt}$
  enum-key attribute-specifier-seq$_{opt}$ *nested-name-specifier identifier*
    enum-base$_{opt}$

opaque-enum-declaration:
  enum-key attribute-specifier-seq$_{opt}$ *identifier enum-base*$_{opt}$ `;`

enum-key:
  `enum`
  `enum class`
  `enum struct`

enum-base:
  `:` *type-specifier-seq*

enumerator-list:
  enumerator-definition
  enumerator-list , *enumerator-definition*
enumerator-definition:
  enumerator
  enumerator = *constant-expression*
enumerator:
  identifier

The optional *attribute-specifier-seq* in the *enum-head* and the *opaque-enum-declaration* appertains to the enumeration; the attributes in that *attribute-specifier-seq* are thereafter considered attributes of the enumeration whenever it is named. A : following "`enum` *identifier*" is parsed as part of an *enum-base*. [*Note:* This resolves a potential ambiguity between the declaration of an enumeration with an *enum-base* and the declaration of an unnamed bit-field of enumeration type. [*Example:*

```
struct S {
  enum E : int {};
  enum E : int {};  // error: redeclaration of enumeration
};
```

— *end example*] — *end note*]

1

The enumeration type declared with an *enum-key* of only `enum` is an unscoped enumeration, and its *enumerator*s are *unscoped enumerators*. The *enum-key*s `enum class` and `enum struct` are semantically equivalent; an enumeration type declared with one of these is a *scoped enumeration*, and its *enumerator*s are *scoped enumerators*. The optional *identifier* shall not be omitted in the declaration of a scoped enumeration. The *type-specifier-seq* of an *enum-base* shall name an integral type; any cv-qualification is ignored. An *opaque-enum-declaration* declaring an unscoped enumeration shall not omit the *enum-base*. The identifiers in an *enumerator-list* are declared as constants, and can appear wherever constants are required. An *enumerator-definition* with = gives the associated *enumerator* the value indicated by the *constant-expression*. If the first *enumerator* has no *initializer*, the value of the corresponding constant is zero. An *enumerator-definition* without an *initializer* gives the *enumerator* the value obtained by increasing the value of the previous *enumerator* by one.

[*Example:*

```
enum { a, b, c=0 };
enum { d, e, f=e+2 };
```

defines `a`, `c`, and `d` to be zero, `b` and `e` to be `1`, and `f` to be `3`. — *end example*]

1

An *opaque-enum-declaration* is either a redeclaration of an enumeration in the current scope or a declaration of a new enumeration. [*Note:* An enumeration declared by an *opaque-enum-declaration* has fixed underlying type and is a complete type. The list of enumerators can be provided in a later redeclaration with an *enum-specifier*. — *end note*] A scoped enumeration shall not be later redeclared as unscoped or with a different underlying type. An unscoped enumeration shall not be later redeclared as scoped and each redeclaration shall include an *enum-base* specifying the same underlying type as in the original declaration.

1

If the *enum-key* is followed by a *nested-name-specifier*, the *enum-specifier* shall refer to an enumeration that was previously declared directly in the class or namespace to which the *nested-name-specifier* refers (i.e., neither inherited nor introduced by a *using-declaration*), and the *enum-specifier* shall appear in a namespace enclosing the previous declaration.

1

Each enumeration defines a type that is different from all other types. Each enumeration also has an underlying type. The underlying type can be explicitly specified using an *enum-base*. For a scoped enumeration type, the underlying type is `int` if it is not explicitly specified. In both of these cases, the underlying type is said to be *fixed*. Following the closing brace of an *enum-specifier*, each enumerator has the type of its enumeration. If the underlying type is fixed, the type of each enumerator prior to the closing brace is the underlying type and the *constant-expression* in the *enumerator-definition* shall be a converted constant expression of the underlying type (5.3643). If the underlying type is not fixed, the type of each enumerator prior to the closing brace is determined as follows:

— If an initializer is specified for an enumerator, the *constant-expression* shall be an integral constant expression (5.3643). If the expression has unscoped enumeration type, the enumerator has the underlying type of that enumeration type, otherwise it has the same type as the expression.

— If no initializer is specified for the first enumerator, its type is an unspecified signed integral type.

— Otherwise the type of the enumerator is the same as that of the preceding enumerator unless the incremented value is not representable in that type, in which case the type is an unspecified integral type sufficient to contain the incremented value. If no such type exists, the program is ill-formed.

1

An enumeration whose underlying type is fixed is an incomplete type from its point of declaration (3.536.1) to immediately after its *enum-base* (if any), at which point it becomes a complete type. An enumeration whose underlying type is not fixed is an incomplete type from its point of declaration to immediately after the closing `}` of its *enum-specifier*, at which point it becomes a complete type.

1

For an enumeration whose underlying type is not fixed, the underlying type is an integral type that can represent all the enumerator values defined in the enumeration. If no integral type can represent all the enumerator values, the enumeration is ill-formed. It is implementation-defined which integral type is used as the underlying type except that the underlying type shall not be larger than `int` unless the value of an enumerator cannot fit in an `int` or `unsigned int`. If the *enumerator-list* is empty, the underlying type is as if the enumeration had a single enumerator with value 0.

1

For an enumeration whose underlying type is fixed, the values of the enumeration are the values of the underlying type. Otherwise, for an enumeration where e_{min} is the smallest enumerator and e_{max} is the largest, the values of the enumeration are the values in the range b_{min} to b_{max}, defined as follows: Let K be 1 for a two's complement representation and 0 for a one's complement or sign-magnitude representation. b_{max} is the smallest value greater than or equal to $max(|e_{min}| - K, |e_{max}|)$ and equal to $2^M - 1$, where M is a non-negative integer. b_{min} is zero if e_{min} is non-negative and $-(b_{max} + K)$ otherwise. The size of the smallest bit-field large enough to hold all the values of the enumeration type is $max(M, 1)$ if b_{min} is zero and $M + 1$ otherwise. It is possible to define an enumeration that has values not defined by any of its enumerators. If the *enumerator-list* is empty, the values of the enumeration are as if the enumeration had a single enumerator with value 0.[95]

1

Two enumeration types are *layout-compatible* if they have the same *underlying type*.

1

95) This set of values is used to define promotion and conversion semantics for the enumeration type. It does not preclude an expression of enumeration type from having a value that falls outside this range.

The value of an enumerator or an object of an unscoped enumeration type is converted to an integer by integral promotion (4.262). [*Example:*

```
enum color { red, yellow, green=20, blue };
color col = red;
color* cp = &col;
if (*cp == blue)              // ...
```

makes `color` a type describing various colors, and then declares `col` as an object of that type, and `cp` as a pointer to an object of that type. The possible values of an object of type `color` are `red`, `yellow`, `green`, `blue`; these values can be converted to the integral values `0`, `1`, `20`, and `21`. Since enumerations are distinct types, objects of type `color` can be assigned only values of type `color`.

```
color c = 1;                  // error: type mismatch,
                              // no conversion from int to color

int i = yellow;               // OK: yellow converted to integral value 1
                              // integral promotion
```

Note that this implicit `enum` to `int` conversion is not provided for a scoped enumeration:

```
enum class Col { red, yellow, green };
int x = Col::red;             // error: no Col to int conversion
Col y = Col::red;
if (y) { }                    // error: no Col to bool conversion
```

— *end example*]

1

Each *enum-name* and each unscoped *enumerator* is declared in the scope that immediately contains the *enum-specifier*. Each scoped *enumerator* is declared in the scope of the enumeration. These names obey the scope rules defined for all names in (3.464) and (3.923).[*Example:*

```
enum direction { left='l', right='r' };

void g()  {
  direction d;                // OK
  d = left;                   // OK
  d = direction::right;       // OK
}

enum class altitude { high='h', low='l' };

void h()  {
  altitude a;                 // OK
  a = high;                   // error: high not in scope
  a = altitude::low;          // OK
}
```

— *end example*] An enumerator declared in class scope can be referred to using the class member access operators (`::`, `.` (dot) and `->` (arrow)), see 5.1194.1. [*Example:*

```
struct X {
  enum direction { left='l', right='r' };
  int f(int i) { return i==left ? 0 : i==right ? 1 : 2; }
};
```

```
void g(X* p) {
  direction d;                  // error: direction not in scope
  int i;
  i = p->f(left);               // error: left not in scope
  i = p->f(X::right);           // OK
  i = p->f(p->left);            // OK
  // ...
}
```

— *end example*]

7.1142 Namespaces [basic.namespace]

1

A namespace is an optionally-named declarative region. The name of a namespace can be used to access entities declared in that namespace; that is, the members of the namespace. Unlike other declarative regions, the definition of a namespace can be split over several parts of one or more translation units.

1

The outermost declarative region of a translation unit is a namespace; see 3.736.1.

7.1149.1 Namespace definition [namespace.def]

1 The grammar for a *namespace-definition* is

namespace-name:
  original-namespace-name
  namespace-alias

original-namespace-name:
  identifier

namespace-definition:
  named-namespace-definition
  unnamed-namespace-definition

named-namespace-definition:
  original-namespace-definition
  extension-namespace-definition

original-namespace-definition:
  `inline`$_{opt}$ `namespace` *identifier* `{` *namespace-body* `}`

extension-namespace-definition:
  `inline`$_{opt}$ `namespace` *original-namespace-name* `{` *namespace-body* `}`

unnamed-namespace-definition:
  `inline`$_{opt}$ `namespace` `{` *namespace-body* `}`

namespace-body:
  declaration-seq$_{opt}$

2

The *identifier* in an *original-namespace-definition* shall not have been previously defined in the declarative region in which the *original-namespace-definition* appears. The *identifier* in an *original-namespace-definition* is the name of the namespace. Subsequently in that declarative region, it is treated as an *original-namespace-name*.

1 The *original-namespace-name* in an *extension-namespace-definition* shall have previously been defined in an *original-namespace-definition* in the same declarative region.

2

Every *namespace-definition* shall appear in the global scope or in a namespace scope (3.736.1).

1 Because a *namespace-definition* contains *declarations* in its *namespace-body* and a *namespace-definition* is itself a *declaration*, it follows that *namespace-definitions* can be nested. [*Example:*

```
namespace Outer {
  int i;
  namespace Inner {
    void f() { i++; }           // Outer::i
    int i;
    void g() { i++; }           // Inner::i
  }
}
```

— *end example*]

2

The *enclosing namespaces* of a declaration are those namespaces in which the declaration lexically appears, except for a redeclaration of a namespace member outside its original namespace (e.g., a definition as specified in 7.1215.0.1). Such a redeclaration has the same enclosing namespaces as the original declaration. [*Example:*

```
namespace Q {
  namespace V {
    void f();    // enclosing namespaces are the global namespace, Q, and Q::V
    class C { void m(); };
  }
  void V::f() { // enclosing namespaces are the global namespace, Q, and Q::V
    extern void h();  // ... so this declares Q::V::h
  }
  void V::C::m() { // enclosing namespaces are the global namespace, Q, and Q::V
  }
}
```

— *end example*]

1

If the optional initial `inline` keyword appears in a *namespace-definition* for a particular namespace, that namespace is declared to be an *inline namespace*. The `inline` keyword may be used on an *extension-namespace-definition* only if it was previously used on the *original-namespace-definition* for that namespace.

1

Members of an inline namespace can be used in most respects as though they were members of the enclosing namespace. Specifically, the inline namespace and its enclosing namespace are both added to the set of associated namespaces used in argument-dependent lookup (3.1092.1) whenever one of them is, and a *using-directive* (7.1416.1) that names the inline namespace is implicitly inserted into the enclosing namespace as for an unnamed namespace (7.1177.0.1). Furthermore, each member of the inline namespace can subsequently be explicitly instantiated (14.1841.1) or explicitly specialized (14.1921.1) as though it were a member of the enclosing namespace. Finally, looking up a name in the enclosing namespace via explicit qualification (3.1363.0.1) will include members of the inline namespace brought in by the *using-directive* even if there are declarations of that name in the enclosing namespace.

1

These properties are transitive: if a namespace `N` contains an inline namespace `M`, which in turn contains an inline namespace `O`, then the members of `O` can be used as though they were members of `M` or `N`. The *inline namespace set* of `N` is the transitive closure of all inline namespaces in `N`. The *enclosing namespace set* of `O`

is the set of namespaces consisting of the innermost non-inline namespace enclosing an inline namespace `0`, together with any intervening inline namespaces.

7.1177.0.1 Unnamed namespaces [namespace.unnamed]

1

An *unnamed-namespace-definition* behaves as if it were replaced by

```
inline_opt namespace unique { /* empty body */ }
using namespace unique ;
namespace unique { namespace-body }
```

where `inline` appears if and only if it appears in the *unnamed-namespace-definition*, all occurrences of ***unique*** in a translation unit are replaced by the same identifier, and this identifier differs from all other identifiers in the entire program.[96] [*Example:*

```
namespace { int i; }            // unique ::i
void f() { i++; }               // unique ::i++

namespace A {
  namespace {
    int i;                      // A:: unique ::i
    int j;                      // A:: unique ::j
  }
  void g() { i++; }             // A:: unique ::i++
}

using namespace A;
void h() {
  i++;                          // error: unique ::i or A:: unique ::i
  A::i++;                       // A:: unique ::i
  j++;                          // A:: unique ::j
}
```

— *end example*]

7.1215.0.1 Namespace member definitions [namespace.memdef]

1

Members (including explicit specializations of templates (14.1921.1)) of a namespace can be defined within that namespace. [*Example:*

```
namespace X {
  void f() { /* ... */ }
}
```

— *end example*]

1

Members of a named namespace can also be defined outside that namespace by explicit qualification (3.1363.0.1) of the name being defined, provided that the entity being defined was already declared in the namespace and the definition appears after the point of declaration in a namespace that encloses the declaration's namespace. [*Example:*

```
namespace Q {
```

96) Although entities in an unnamed namespace might have external linkage, they are effectively qualified by a name unique to their translation unit and therefore can never be seen from any other translation unit.

```
  namespace V {
    void f();
  }
  void V::f() { /* ... */ }      // OK
  void V::g() { /* ... */ }      // error: g() is not yet a member of V
  namespace V {
    void g();
  }
}

namespace R {
  void Q::V::g() { /* ... */ }  // error: R doesn't enclose Q
}
```

— *end example*]

1

Every name first declared in a namespace is a member of that namespace. If a `friend` declaration in a non-local class first declares a class, function, class template or function template[97] the friend is a member of the innermost enclosing namespace. The `friend` declaration does not by itself make the name visible to unqualified lookup (3.952.1) or qualified lookup (3.1236.1). [*Note:* The name of the friend will be visible in its namespace if a matching declaration is provided at namespace scope (either before or after the class definition granting friendship). — *end note*] If a friend function or function template is called, its name may be found by the name lookup that considers functions from namespaces and classes associated with the types of the function arguments (3.1092.1). If the name in a `friend` declaration is neither qualified nor a *template-id* and the declaration is a function or an *elaborated-type-specifier*, the lookup to determine whether the entity has been previously declared shall not consider any scopes outside the innermost enclosing namespace. [*Note:* The other forms of `friend` declarations cannot declare a new member of the innermost enclosing namespace and thus follow the usual lookup rules. — *end note*] [*Example:*

```
// Assume f and g have not yet been declared.
void h(int);
template <class T> void f2(T);
namespace A {
  class X {
    friend void f(X);            // A::f(X) is a friend
    class Y {
      friend void g();           // A::g is a friend
      friend void h(int);        // A::h is a friend
                                 // ::h not considered
      friend void f2<>(int);     // ::f2<>(int) is a friend
    };
  };

  // A::f, A::g and A::h are not visible here
  X x;
  void g() { f(x); }             // definition of A::g
  void f(X) { /* ...  */}        // definition of A::f
  void h(int) { /* ...  */ }     // definition of A::h
  // A::f, A::g and A::h are visible here and known to be friends
}

using A::x;
```

97) this implies that the name of the class or function is unqualified.

```
void h() {
  A::f(x);
  A::X::f(x);                    // error: f is not a member of A::X
  A::X::Y::g();                  // error: g is not a member of A::X::Y
}
```

— *end example*]

7.1306.1 Namespace alias [namespace.alias]

1 A *namespace-alias-definition* declares an alternate name for a namespace according to the following grammar:

namespace-alias:
identifier

namespace-alias-definition:
`namespace` *identifier* `=` *qualified-namespace-specifier* `;`

qualified-namespace-specifier:
nested-name-specifier$_{opt}$ *namespace-name*

2

The *identifier* in a *namespace-alias-definition* is a synonym for the name of the namespace denoted by the *qualified-namespace-specifier* and becomes a *namespace-alias*. [*Note:* When looking up a *namespace-name* in a *namespace-alias-definition*, only namespace names are considered, see 3.1457.1. — *end note*]

1 In a declarative region, a *namespace-alias-definition* can be used to redefine a *namespace-alias* declared in that declarative region to refer only to the namespace to which it already refers. [*Example:* the following declarations are well-formed:

```
namespace Company_with_very_long_name { /* ... */ }
namespace CWVLN = Company_with_very_long_name;
namespace CWVLN = Company_with_very_long_name;          // OK: duplicate
namespace CWVLN = CWVLN;
```

— *end example*]

2

A *namespace-name* or *namespace-alias* shall not be declared as the name of any other entity in the same declarative region. A *namespace-name* defined at global scope shall not be declared as the name of any other entity in any global scope of the program. No diagnostic is required for a violation of this rule by declarations in different translation units.

7.1311.1 The `using` declaration [namespace.udecl]

1

A *using-declaration* introduces a name into the declarative region in which the *using-declaration* appears.

using-declaration:
`using` `typename`$_{opt}$ *nested-name-specifier unqualified-id* `;`
`using` `::` *unqualified-id* `;`

The member name specified in a *using-declaration* is declared in the declarative region in which the *using-declaration* appears. [*Note:* Only the specified name is so declared; specifying an enumeration name in a *using-declaration* does not declare its enumerators in the *using-declaration*'s declarative region. — *end note*] If a *using-declaration* names a constructor (3.1282.0.1), it implicitly declares a set of constructors in the class in which the *using-declaration* appears (12.2400); otherwise the name specified in a *using-declaration* is a synonym for a set of declarations in another namespace or class.

1

Every *using-declaration* is a *declaration* and a *member-declaration* and so can be used in a class definition. [*Example:*

```
struct B {
  void f(char);
  void g(char);
  enum E { e };
  union { int x; };
};

struct D : B {
  using B::f;
  void f(int) { f('c'); }       // calls B::f(char)
  void g(int) { g('c'); }       // recursively calls D::g(int)
};
```

— *end example*]

1

In a *using-declaration* used as a *member-declaration*, the *nested-name-specifier* shall name a base class of the class being defined. If such a *using-declaration* names a constructor, the *nested-name-specifier* shall name a direct base class of the class being defined; otherwise it introduces the set of declarations found by member name lookup (10.52, 3.1282.0.1). [*Example:*

```
class C {
  int g();
};

class D2 : public B {
  using B::f;                   // OK: B is a base of D2
  using B::e;                   // OK: e is an enumerator of base B
  using B::x;                   // OK: x is a union member of base B
  using C::g;                   // error: C isn't a base of D2
};
```

— *end example*]

1

[*Note:* Since destructors do not have names, a *using-declaration* cannot refer to a destructor for a base class. Since specializations of member templates for conversion functions are not found by name lookup, they are not considered when a *using-declaration* specifies a conversion function (14.641.1). — *end note*] If an assignment operator brought from a base class into a derived class scope has the signature of a copy/move assignment operator for the derived class (12.1577), the *using-declaration* does not by itself suppress the implicit declaration of the derived class assignment operator; the copy/move assignment operator from the base class is hidden or overridden by the implicitly-declared copy/move assignment operator of the derived class, as described below.

1 A *using-declaration* shall not name a *template-id*. [*Example:*

```
struct A {
  template <class T> void f(T);
  template <class T> struct X { };
};
struct B : A {
  using A::f<double>;           // ill-formed
  using A::X<int>;              // ill-formed
};
```

— *end example*]

2 A *using-declaration* shall not name a namespace.

3

A *using-declaration* shall not name a scoped enumerator.

1

A *using-declaration* for a class member shall be a *member-declaration*. [*Example:*

```
struct X {
  int i;
  static int s;
};

void f() {
  using X::i;        // error: X::i is a class member
                     // and this is not a member declaration.
  using X::s;        // error: X::s is a class member
                     // and this is not a member declaration.
}
```

— *end example*]

1 Members declared by a *using-declaration* can be referred to by explicit qualification just like other member names (3.1363.0.1). In a *using-declaration*, a prefix `::` refers to the global namespace. [*Example:*

```
void f();

namespace A {
  void g();
}

namespace X {
  using ::f;         // global f
  using A::g;        // A's g
}

void h()
{
  X::f();            // calls ::f
  X::g();            // calls A::g
}
```

— *end example*]

2

A *using-declaration* is a *declaration* and can therefore be used repeatedly where (and only where) multiple declarations are allowed. [*Example:*

```
namespace A {
  int i;
}

namespace A1 {
  using A::i;
  using A::i;        // OK: double declaration
}
```

```
void f() {
  using A::i;
  using A::i;        // error: double declaration
}

struct B {
  int i;
};

struct X : B {
  using B::i;
  using B::i;        // error: double member declaration
};
```

— *end example*]

1 Members added to the namespace after the *using-declaration* are not considered when a use of the name is made. [*Note:* Thus, additional overloads added after the *using-declaration* are ignored, but default function arguments (8.545.1), default template arguments (14.97), and template specializations (14.812.1, 14.1921.1) are considered. — *end note*] [*Example:*

```
namespace A {
  void f(int);
}

using A::f;          // f is a synonym for A::f;
                     // that is, for A::f(int).
namespace A {
  void f(char);
}

void foo() {
  f('a');            // calls f(int),
}                    // even though f(char) exists.

void bar() {
  using A::f;        // f is a synonym for A::f;
                     // that is, for A::f(int) and A::f(char).
  f('a');            // calls f(char)
}
```

— *end example*]

2 [*Note:* Partial specializations of class templates are found by looking up the primary class template and then considering all partial specializations of that template. If a *using-declaration* names a class template, partial specializations introduced after the *using-declaration* are effectively visible because the primary template is visible (14.812.1). — *end note*]

3

Since a *using-declaration* is a declaration, the restrictions on declarations of the same name in the same declarative region (3.464) also apply to *using-declarations*. [*Example:*

```
namespace A {
  int x;
}
```

```
namespace B {
  int i;
  struct g { };
  struct x { };
  void f(int);
  void f(double);
  void g(char);      // OK: hides struct g
}

void func() {
  int i;
  using B::i;        // error: i declared twice
  void f(char);
  using B::f;        // OK: each f is a function
  f(3.5);            // calls B::f(double)
  using B::g;
  g('a');            // calls B::g(char)
  struct g g1;       // g1 has class type B::g
  using B::x;
  using A::x;        // OK: hides struct B::x
  x = 99;            // assigns to A::x
  struct x x1;       // x1 has class type B::x
}
```

— *end example*]

1

If a function declaration in namespace scope or block scope has the same name and the same parameter-type-list (8.360.1) as a function introduced by a *using-declaration*, and the declarations do not declare the same function, the program is ill-formed. If a function template declaration in namespace scope has the same name, parameter-type-list, return type, and template parameter list as a function template introduced by a *using-declaration*, the program is ill-formed. [*Note:* Two *using-declaration*s may introduce functions with the same name and the same parameter-type-list. If, for a call to an unqualified function name, function overload resolution selects the functions introduced by such *using-declaration*s, the function call is ill-formed. [*Example:*

```
namespace B {
  void f(int);
  void f(double);
}
namespace C {
  void f(int);
  void f(double);
  void f(char);
}

void h() {
  using B::f;        // B::f(int) and B::f(double)
  using C::f;        // C::f(int), C::f(double), and C::f(char)
  f('h');            // calls C::f(char)
  f(1);              // error: ambiguous: B::f(int) or C::f(int)?
  void f(int);       // error: f(int) conflicts with C::f(int) and B::f(int)
}
```

— *end example*] — *end note*]

1

When a *using-declaration* brings names from a base class into a derived class scope, member functions and member function templates in the derived class override and/or hide member functions and member function templates with the same name, parameter-type-list (8.360.1), cv-qualification, and *ref-qualifier* (if any) in a base class (rather than conflicting). [*Note:* For *using-declarations* that name a constructor, see 12.2400. — *end note*] [*Example:*

```
struct B {
  virtual void f(int);
  virtual void f(char);
  void g(int);
  void h(int);
};

struct D : B {
  using B::f;
  void f(int);       // OK: D::f(int) overrides B::f(int);

  using B::g;
  void g(char);      // OK

  using B::h;
  void h(int);       // OK: D::h(int) hides B::h(int)
};

void k(D* p)
{
  p->f(1);           // calls D::f(int)
  p->f('a');         // calls B::f(char)
  p->g(1);           // calls B::g(int)
  p->g('a');         // calls D::g(char)
}
```

— *end example*]

1

For the purpose of overload resolution, the functions which are introduced by a *using-declaration* into a derived class will be treated as though they were members of the derived class. In particular, the implicit `this` parameter shall be treated as if it were a pointer to the derived class rather than to the base class. This has no effect on the type of the function, and in all other respects the function remains a member of the base class.

1

The access rules for inheriting constructors are specified in 12.2400; otherwise all instances of the name mentioned in a *using-declaration* shall be accessible. In particular, if a derived class uses a *using-declaration* to access a member of a base class, the member name shall be accessible. If the name is that of an overloaded member function, then all functions named shall be accessible. The base class members mentioned by a *using-declaration* shall be visible in the scope of at least one of the direct base classes of the class where the *using-declaration* is specified. [*Note:* Because a *using-declaration* designates a base class member (and not a member subobject or a member function of a base class subobject), a *using-declaration* cannot be used to resolve inherited member ambiguities. For example,

```
struct A { int x(); };
struct B : A { };
struct C : A {
```

```
  using A::x;
  int x(int);
};

struct D : B, C {
  using C::x;
  int x(double);
};
int f(D* d) {
  return d->x();     // ambiguous: B::x or C::x
}
```

— *end note*]

1

The alias created by the *using-declaration* has the usual accessibility for a *member-declaration*. [*Note:* A *using-declaration* that names a constructor does not create aliases; see 12.2400 for the pertinent accessibility rules. — *end note*] [*Example:*

```
class A {
private:
    void f(char);
public:
    void f(int);
protected:
    void g();
};

class B : public A {
  using A::f;       // error: A::f(char) is inaccessible
public:
  using A::g;       // B::g is a public synonym for A::g
};
```

— *end example*]

1

If a *using-declaration* uses the keyword `typename` and specifies a dependent name (14.1257.1), the name introduced by the *using-declaration* is treated as a *typedef-name* (7.235.1).

7.1416.1 Using directive [namespace.udir]

using-directive:
attribute-specifier-seq$_{opt}$ `using namespace` *nested-name-specifier*$_{opt}$ *namespace-name* ;

1

A *using-directive* shall not appear in class scope, but may appear in namespace scope or in block scope. [*Note:* When looking up a *namespace-name* in a *using-directive*, only namespace names are considered, see 3.1457.1. — *end note*] The optional *attribute-specifier-seq* appertains to the *using-directive*.

1

A *using-directive* specifies that the names in the nominated namespace can be used in the scope in which the *using-directive* appears after the *using-directive*. During unqualified name lookup (3.952.1), the names appear as if they were declared in the nearest enclosing namespace which contains both the *using-directive* and the nominated namespace. [*Note:* In this context, "contains" means "contains directly or indirectly". — *end note*]

1

A *using-directive* does not add any members to the declarative region in which it appears. [*Example:*

```
namespace A {
  int i;
  namespace B {
    namespace C {
      int i;
    }
    using namespace A::B::C;
    void f1() {
      i = 5;        // OK, C::i visible in B and hides A::i
    }
  }
  namespace D {
    using namespace B;
    using namespace C;
    void f2() {
      i = 5;        // ambiguous, B::C::i or A::i?
    }
  }
  void f3() {
    i = 5;          // uses A::i
  }
}
void f4() {
  i = 5;            // ill-formed; neither i is visible
}
```

— *end example*]

1

For unqualified lookup (3.952.1), the *using-directive* is transitive: if a scope contains a *using-directive* that nominates a second namespace that itself contains *using-directive*s, the effect is as if the *using-directive*s from the second namespace also appeared in the first. [*Note:* For qualified lookup, see 3.1363.0.1. — *end note*] [*Example:*

```
namespace M {
  int i;
}

namespace N {
  int i;
  using namespace M;
}

void f() {
  using namespace N;
  i = 7;            // error: both M::i and N::i are visible
}
```

For another example,

```
namespace A {
  int i;
}
```

```
namespace B {
  int i;
  int j;
  namespace C {
    namespace D {
      using namespace A;
      int j;
      int k;
      int a = i;    // B::i hides A::i
    }
    using namespace D;
    int k = 89;     // no problem yet
    int l = k;      // ambiguous: C::k or D::k
    int m = i;      // B::i hides A::i
    int n = j;      // D::j hides B::j
  }
}
```

— *end example*]

1 If a namespace is extended by an *extension-namespace-definition* after a *using-directive* for that namespace is given, the additional members of the extended namespace and the members of namespaces nominated by *using-directive*s in the *extension-namespace-definition* can be used after the *extension-namespace-definition*.

2 If name lookup finds a declaration for a name in two different namespaces, and the declarations do not declare the same entity and do not declare functions, the use of the name is ill-formed. [*Note:* In particular, the name of a variable, function or enumerator does not hide the name of a class or enumeration declared in a different namespace. For example,

```
namespace A {
  class X { };
  extern "C"   int g();
  extern "C++" int h();
}
namespace B {
  void X(int);
  extern "C"   int g();
  extern "C++" int h(int);
}
using namespace A;
using namespace B;

void f() {
  X(1);             // error: name X found in two namespaces
  g();              // okay: name g refers to the same entity
  h();              // okay: overload resolution selects A::h
}
```

— *end note*]

1 During overload resolution, all functions from the transitive search are considered for argument matching. The set of declarations found by the transitive search is unordered. [*Note:* In particular, the order in which namespaces were considered and the relationships among the namespaces implied by the *using-directive*s do not cause preference to be given to any of the declarations found by the search. — *end note*] An ambiguity exists if the best match finds two functions with the same signature, even if one is in a namespace reachable

through *using-directives* in the namespace of the other.[98] [*Example:*

```
namespace D {
  int d1;
  void f(char);
}
using namespace D;

int d1;             // OK: no conflict with D::d1

namespace E {
  int e;
  void f(int);
}

namespace D {       // namespace extension
  int d2;
  using namespace E;
  void f(int);
}

void f() {
  d1++;             // error: ambiguous ::d1 or D::d1?
  ::d1++;           // OK
  D::d1++;          // OK
  d2++;             // OK: D::d2
  e++;              // OK: E::e
  f(1);             // error: ambiguous: D::f(int) or E::f(int)?
  f('a');           // OK: D::f(char)
}
```

— *end example*]

7.1473 The `asm` declaration [dcl.asm]

1

An `asm` declaration has the form

asm-definition:
`asm` (*string-literal*) ;

The `asm` declaration is conditionally-supported; its meaning is implementation-defined. [*Note:* Typically it is used to pass information through the implementation to an assembler. — *end note*]

7.1477 Linkage specifications [dcl.link]

1

All function types, function names with external linkage, and variable names with external linkage have a *language linkage*. [*Note:* Some of the properties associated with an entity with language linkage are specific to each implementation and are not described here. For example, a particular language linkage may be associated with a particular form of representing names of objects and functions with external linkage, or with a particular calling convention, etc. — *end note*] The default language linkage of all function types, function names, and variable names is C++ language linkage. Two function types with different language linkages are distinct types even if they are otherwise identical.

98) During name lookup in a class hierarchy, some ambiguities may be resolved by considering whether one member hides the other along some paths (10.52). There is no such disambiguation when considering the set of names found as a result of following *using-directives*.

1

Linkage (3.1459) between C++ and non-C++ code fragments can be achieved using a *linkage-specification*:

linkage-specification:
`extern` *string-literal* `{` *declaration-seq*$_{opt}$`}`
`extern` *string-literal declaration*

The *string-literal* indicates the required language linkage. This International Standard specifies the semantics for the *string-literals* `"C"` and `"C++"`. Use of a *string-literal* other than `"C"` or `"C++"` is conditionally-supported, with implementation-defined semantics. [*Note:* Therefore, a linkage-specification with a *string-literal* that is unknown to the implementation requires a diagnostic. — *end note*] [*Note:* It is recommended that the spelling of the *string-literal* be taken from the document defining that language. For example, `Ada` (not `ADA`) and `Fortran` or `FORTRAN`, depending on the vintage. — *end note*]

1

Every implementation shall provide for linkage to functions written in the C programming language, `"C"`, and linkage to C++ functions, `"C++"`. [*Example:*

```
complex sqrt(complex);          // C++ linkage by default
extern "C" {
  double sqrt(double);          // C linkage
}
```

— *end example*]

1

Linkage specifications nest. When linkage specifications nest, the innermost one determines the language linkage. A linkage specification does not establish a scope. A *linkage-specification* shall occur only in namespace scope (3.464). In a *linkage-specification*, the specified language linkage applies to the function types of all function declarators, function names with external linkage, and variable names with external linkage declared within the *linkage-specification*. [*Example:*

```
extern "C" void f1(void(*pf)(int));
                                // the name f1 and its function type have C language
                                // linkage; pf is a pointer to a C function
extern "C" typedef void FUNC();
FUNC f2;                        // the name f2 has C++ language linkage and the
                                // function's type has C language linkage
extern "C" FUNC f3;             // the name of function f3 and the function's type
                                // have C language linkage
void (*pf2)(FUNC*);             // the name of the variable pf2 has C++ linkage and
                                // the type of pf2 is pointer to C++ function that
                                // takes one parameter of type pointer to C function
extern "C" {
  static void f4();             // the name of the function f4 has
                                // internal linkage (not C language
                                // linkage) and the function's type
                                // has C language linkage.
}

extern "C" void f5() {
  extern void f4();             // OK: Name linkage (internal)
                                // and function type linkage (C
                                // language linkage) obtained from
                                // previous declaration.
}
```

```
extern void f4();                // OK: Name linkage (internal)
                                 // and function type linkage (C
                                 // language linkage) obtained from
                                 // previous declaration.

void f6() {
  extern void f4();              // OK: Name linkage (internal)
                                 // and function type linkage (C
                                 // language linkage) obtained from
                                 // previous declaration.
}
```

— *end example*] A C language linkage is ignored in determining the language linkage of the names of class members and the function type of class member functions. [*Example:*

```
extern "C" typedef void FUNC_c();
class C {
   void mf1(FUNC_c*);            // the name of the function mf1 and the member
                                 // function's type have C++ language linkage; the
                                 // parameter has type pointer to C function
   FUNC_c mf2;                   // the name of the function mf2 and the member
                                 // function's type have C++ language linkage
   static FUNC_c* q;             // the name of the data member q has C++ language
                                 // linkage and the data member's type is pointer to
                                 // C function
};

extern "C" {
  class X {
  void mf();                     // the name of the function mf and the member
                                 // function's type have C++ language linkage
  void mf2(void(*)());           // the name of the function mf2 has C++ language
                                 // linkage; the parameter has type pointer to
                                 // C function
  };
}
```

— *end example*]

1

If two declarations declare functions with the same name and *parameter-type-list* (8.360.1) to be members of the same namespace or declare objects with the same name to be members of the same namespace and the declarations give the names different language linkages, the program is ill-formed; no diagnostic is required if the declarations appear in different translation units. Except for functions with C++ linkage, a function declaration without a linkage specification shall not precede the first linkage specification for that function. A function can be declared without a linkage specification after an explicit linkage specification has been seen; the linkage explicitly specified in the earlier declaration is not affected by such a function declaration.

1

At most one function with a particular name can have C language linkage. Two declarations for a function with C language linkage with the same function name (ignoring the namespace names that qualify it) that appear in different namespace scopes refer to the same function. Two declarations for a variable with C language linkage with the same name (ignoring the namespace names that qualify it) that appear in different namespace scopes refer to the same variable. An entity with C language linkage shall not be declared with the same name as an entity in global scope, unless both declarations denote the same entity; no diagnostic

is required if the declarations appear in different translation units. A variable with C language linkage shall not be declared with the same name as a function with C language linkage (ignoring the namespace names that qualify the respective names); no diagnostic is required if the declarations appear in different translation units. [*Note:* Only one definition for an entity with a given name with C language linkage may appear in the program (see 3.91); this implies that such an entity must not be defined in more than one namespace scope. — *end note*] [*Example:*

```
int x;
namespace A {
  extern "C" int f();
  extern "C" int g() { return 1; }
  extern "C" int h();
  extern "C" int x();                // ill-formed: same name as global-space object x
}

namespace B {
  extern "C" int f();                // A::f and B::f refer to the same function
  extern "C" int g() { return 1; }   // ill-formed, the function g
                                     // with C language linkage has two definitions
}

int A::f() { return 98; }            //definition for the function f with C language linkage
extern "C" int h() { return 97; }    // definition for the function h with C language linkage
                                     // A::h and ::h refer to the same function
```

— *end example*]

1

A declaration directly contained in a *linkage-specification* is treated as if it contains the `extern` specifier (7.49.1) for the purpose of determining the linkage of the declared name and whether it is a definition. Such a declaration shall not specify a storage class. [*Example:*

```
extern "C" double f();
static double f();                   // error
extern "C" int i;                    // declaration
extern "C" {
  int i;                             // definition
}
extern "C" static void g();          // error
```

— *end example*]

1 [*Note:* Because the language linkage is part of a function type, when indirecting through a pointer to C function, the function to which the resulting lvalue refers is considered a C function. — *end note*]

2

Linkage from C++ to objects defined in other languages and to objects defined in C++ from other languages is implementation-defined and language-dependent. Only where the object layout strategies of two language implementations are similar enough can such linkage be achieved.

7.1546 Attributes [dcl.attr]

7.1546.1 Attribute syntax and semantics [dcl.attr.grammar]

1 Attributes specify additional information for various source constructs such as types, variables, names, blocks, or translation units.

attribute-specifier-seq:
  attribute-specifier-seq$_{opt}$ *attribute-specifier*

attribute-specifier:
  `[ [` *attribute-list* `] ]`
  alignment-specifier

alignment-specifier:
  `alignas (` *type-id* `...`$_{opt}$`)`
  `alignas (` *constant-expression* `...`$_{opt}$`)`

attribute-list:
  attribute$_{opt}$
  attribute-list `,` *attribute*$_{opt}$
  attribute `...`
  attribute-list `,` *attribute* `...`

attribute:
  attribute-token attribute-argument-clause$_{opt}$

attribute-token:
  identifier
  attribute-scoped-token

attribute-scoped-token:
  attribute-namespace `::` *identifier*

attribute-namespace:
  identifier

attribute-argument-clause:
  `(` *balanced-token-seq* `)`

balanced-token-seq:
  balanced-token$_{opt}$
  balanced-token-seq balanced-token

balanced-token:
  `(` *balanced-token-seq* `)`
  `[` *balanced-token-seq* `]`
  `{` *balanced-token-seq* `}`
  any *token* other than a parenthesis, a bracket, or a brace

2 [*Note:* For each individual attribute, the form of the *balanced-token-seq* will be specified. — *end note*]

3

In an *attribute-list*, an ellipsis may appear only if that *attribute*'s specification permits it. An *attribute* followed by an ellipsis is a pack expansion (14.703.1). An *attribute-specifier* that contains no *attribute*s has no effect. The order in which the *attribute-tokens* appear in an *attribute-list* is not significant. If a keyword (2.287) or an alternative token (2.236) that satisfies the syntactic requirements of an *identifier* (2.268) is contained in an *attribute-token*, it is considered an identifier. No name lookup (3.923) is performed on any of the identifiers contained in an *attribute-token*. The *attribute-token* determines additional requirements on the *attribute-argument-clause* (if any). The use of an *attribute-scoped-token* is conditionally-supported, with implementation-defined behavior. [*Note:* Each implementation should choose a distinctive name for the *attribute-namespace* in an *attribute-scoped-token*. — *end note*]

1

Each *attribute-specifier-seq* is said to *appertain* to some entity or statement, identified by the syntactic context where it appears (Clause 6, Clause 7, Clause 8). If an *attribute-specifier-seq* that appertains to some entity or statement contains an *attribute* that is not allowed to apply to that entity or statement, the program is ill-formed. If an *attribute-specifier-seq* appertains to a friend declaration (11.94), that declaration shall be a definition. No *attribute-specifier-seq* shall appertain to an explicit instantiation (14.1841.1).

1

For an *attribute-token* not specified in this International Standard, the behavior is implementation-defined.

1

Two consecutive left square bracket tokens shall appear only when introducing an *attribute-specifier*. [*Note:* If two consecutive left square brackets appear where an *attribute-specifier* is not allowed, the program is ill-formed even if the brackets match an alternative grammar production. — *end note*] [*Example:*

```
int p[10];
void f() {
  int x = 42, y[5];
  int(p[[x] { return x; }()]);   // error: invalid attribute on a nested
                                 // declarator-id and not a function-style cast of
                                 // an element of p.
  y[[] { return 2; }()] = 2;     // error even though attributes are not allowed
                                 // in this context.
}
```

— *end example*]

7.1556.1 Alignment specifier [dcl.align]

1

An *alignment-specifier* may be applied to a variable or to a class data member, but it shall not be applied to a bit-field, a function parameter, an *exception-declaration* (15.146), or a variable declared with the `register` storage class specifier. An *alignment-specifier* may also be applied to the declaration or definition of a class (in an *elaborated-type-specifier* (7.808.0.1) or *class-head* (Clause 9), respectively) and to the declaration or definition of an enumeration (in an *opaque-enum-declaration* or *enum-head*, respectively (7.1001)). An *alignment-specifier* with an ellipsis is a pack expansion (14.703.1).

1

When the *alignment-specifier* is of the form `alignas(` *constant-expression* `)`:

— the *constant-expression* shall be an integral constant expression

— if the constant expression evaluates to a fundamental alignment, the alignment requirement of the declared entity shall be the specified fundamental alignment

— if the constant expression evaluates to an extended alignment and the implementation supports that alignment in the context of the declaration, the alignment of the declared entity shall be that alignment

— if the constant expression evaluates to an extended alignment and the implementation does not support that alignment in the context of the declaration, the program is ill-formed

— if the constant expression evaluates to zero, the alignment specifier shall have no effect

— otherwise, the program is ill-formed.

1 When the *alignment-specifier* is of the form `alignas(` *type-id* `)`, it shall have the same effect as `alignas(` `alignof(`*type-id* `))` (5.2747.1).

2 When multiple *alignment-specifier*s are specified for an entity, the alignment requirement shall be set to the strictest specified alignment.

3

The combined effect of all *alignment-specifier*s in a declaration shall not specify an alignment that is less strict than the alignment that would be required for the entity being declared if all *alignment-specifier*s were omitted (including those in other declarations).

1 If the defining declaration of an entity has an *alignment-specifier*, any non-defining declaration of that entity shall either specify equivalent alignment or have no *alignment-specifier*. Conversely, if any declaration of an entity has an *alignment-specifier*, every defining declaration of that entity shall specify an equivalent alignment. No diagnostic is required if declarations of an entity have different *alignment-specifier*s in different translation units.

[*Example:*

```
// Translation unit #1:
struct S { int x; } s, p = &s;

// Translation unit #2:
struct alignas(16) S;          // error: definition of S lacks alignment; no
extern S* p;                   // diagnostic required
```

— *end example*]

2 [*Example:* An aligned buffer with an alignment requirement of `A` and holding `N` elements of type `T` other than `char`, `signed char`, or `unsigned char` can be declared as:

```
alignas(T) alignas(A) T buffer[N];
```

Specifying `alignas(T)` ensures that the final requested alignment will not be weaker than `alignof(T)`, and therefore the program will not be ill-formed. — *end example*]

3 [*Example:*

```
alignas(double) void f();                        // error: alignment applied to function
alignas(double) unsigned char c[sizeof(double)]; // array of characters, suitably aligned for a double
extern unsigned char c[sizeof(double)];          // no alignas necessary
alignas(float)
  extern unsigned char c[sizeof(double)];        // error: different alignment in declaration
```

— *end example*]

7.1569.1 Noreturn attribute [dcl.attr.noreturn]

1

The *attribute-token* `noreturn` specifies that a function does not return. It shall appear at most once in each *attribute-list* and no *attribute-argument-clause* shall be present. The attribute may be applied to the *declarator-id* in a function declaration. The first declaration of a function shall specify the `noreturn` attribute if any declaration of that function specifies the `noreturn` attribute. If a function is declared with the `noreturn` attribute in one translation unit and the same function is declared without the `noreturn` attribute in another translation unit, the program is ill-formed; no diagnostic required.

1

If a function `f` is called where `f` was previously declared with the `noreturn` attribute and `f` eventually returns, the behavior is undefined. [*Note:* The function may terminate by throwing an exception. — *end note*] [*Note:* Implementations are encouraged to issue a warning if a function marked `[[noreturn]]` might return. — *end note*]

1 [*Example:*

```
[[ noreturn ]] void f() {
  throw "error";        // OK
```

```
}

[[ noreturn ]] void q(int i) { // behavior is undefined if called with an argument <= 0
  if (i > 0)
    throw "positive";
}
```

— *end example*]

7.1574.1 Carries dependency attribute [dcl.attr.depend]

1

The *attribute-token* `carries_dependency` specifies dependency propagation into and out of functions. It shall appear at most once in each *attribute-list* and no *attribute-argument-clause* shall be present. The attribute may be applied to the *declarator-id* of a *parameter-declaration* in a function declaration or lambda, in which case it specifies that the initialization of the parameter carries a dependency to (1.859) each lvalue-to-rvalue conversion (4.127) of that object. The attribute may also be applied to the *declarator-id* of a function declaration, in which case it specifies that the return value, if any, carries a dependency to the evaluation of the function call expression.

1 The first declaration of a function shall specify the `carries_dependency` attribute for its *declarator-id* if any declaration of the function specifies the `carries_dependency` attribute. Furthermore, the first declaration of a function shall specify the `carries_dependency` attribute for a parameter if any declaration of that function specifies the `carries_dependency` attribute for that parameter. If a function or one of its parameters is declared with the `carries_dependency` attribute in its first declaration in one translation unit and the same function or one of its parameters is declared without the `carries_dependency` attribute in its first declaration in another translation unit, the program is ill-formed; no diagnostic required.

2 [*Note:* The `carries_dependency` attribute does not change the meaning of the program, but may result in generation of more efficient code. — *end note*]

3 [*Example:*

```
/* Translation unit A. */

struct foo { int* a; int* b; };
std::atomic<struct foo *> foo_head[10];
int foo_array[10][10];

[[carries_dependency]] struct foo* f(int i) {
  return foo_head[i].load(memory_order_consume);
}

int g(int* x, int* y [[carries_dependency]]) {
  return kill_dependency(foo_array[*x][*y]);
}

/* Translation unit B. */

[[carries_dependency]] struct foo* f(int i);
int g(int* x, int* y [[carries_dependency]]);

int c = 3;

void h(int i) {
  struct foo* p;
```

```
  p = f(i);
  do_something_with(g(&c, p->a));
  do_something_with(g(p->a, &c));
}
```

4 The `carries_dependency` attribute on function `f` means that the return value carries a dependency out of `f`, so that the implementation need not constrain ordering upon return from `f`. Implementations of `f` and its caller may choose to preserve dependencies instead of emitting hardware memory ordering instructions (a.k.a. fences).

5 Function `g`'s second parameter has a `carries_dependency` attribute, but its first parameter does not. Therefore, function `h`'s first call to `g` carries a dependency into `g`, but its second call does not. The implementation might need to insert a fence prior to the second call to `g`.

— *end example*]

7.1576.1 Deprecated attribute [dcl.attr.deprecated]

1

The *attribute-token* `deprecated` can be used to mark names and entities whose use is still allowed, but is discouraged for some reason. [*Note:* in particular, `deprecated` is appropriate for names and entities that are deemed obsolescent or unsafe. — *end note*] It shall appear at most once in each *attribute-list*. An *attribute-argument-clause* may be present and, if present, it shall have the form:

```
( string-literal )
```

[*Note:* the *string-literal* in the *attribute-argument-clause* could be used to explain the rationale for deprecation and/or to suggest a replacing entity. — *end note*]

1

The attribute may be applied to the declaration of a class, a *typedef-name*, a variable, a non-static data member, a function, an enumeration, or a template specialization.

1

A name or entity declared without the `deprecated` attribute can later be re-declared with the attribute and vice-versa. [*Note:* Thus, an entity initially declared without the attribute can be marked as deprecated by a subsequent redeclaration. However, after an entity is marked as deprecated, later redeclarations do not un-deprecate the entity. — *end note*] Redeclarations using different forms of the attribute (with or without the *attribute-argument-clause* or with different *attribute-argument-clauses*) are allowed.

1

[*Note:* Implementations may use the `deprecated` attribute to produce a diagnostic message in case the program refers to a name or entity other than to declare it, after a declaration that specifies the attribute. The diagnostic message may include the text provided within the *attribute-argument-clause* of any `deprecated` attribute applied to the name or entity. — *end note*]

8 Declarators [dcl.decl]

1

A declarator declares a single variable, function, or type, within a declaration. The *init-declarator-list* appearing in a declaration is a comma-separated sequence of declarators, each of which can have an initializer.

init-declarator-list:
  init-declarator
  init-declarator-list **,** *init-declarator*

init-declarator:
  declarator initializer$_{opt}$

1

The three components of a *simple-declaration* are the attributes (7.1546), the specifiers (*decl-specifier-seq*; 7.40) and the declarators (*init-declarator-list*). The specifiers indicate the type, storage class or other properties of the entities being declared. The declarators specify the names of these entities and (optionally) modify the type of the specifiers with operators such as `*` (pointer to) and `()` (function returning). Initial values can also be specified in a declarator; initializers are discussed in 8.821 and 12.1011.

1

Each *init-declarator* in a declaration is analyzed separately as if it was in a declaration by itself.[99]

1

Declarators have the syntax

declarator:
  ptr-declarator
  noptr-declarator parameters-and-qualifiers trailing-return-type

ptr-declarator:
  noptr-declarator
  ptr-operator ptr-declarator

99) A declaration with several declarators is usually equivalent to the corresponding sequence of declarations each with a single declarator. That is

```
T D1, D2, ...  Dn;
```

is usually equivalent to

```
T D1; T D2; ...  T Dn;
```

where `T` is a *decl-specifier-seq* and each `Di` is an *init-declarator*. An exception occurs when a name introduced by one of the *declarator*s hides a type name used by the *decl-specifiers*, so that when the same *decl-specifiers* are used in a subsequent declaration, they do not have the same meaning, as in

```
struct S  ...  ;
S S, T; // declare two instances of struct S
```

which is not equivalent to

```
struct S  ...  ;
S S;
S T; // error
```

Another exception occurs when `T` is `auto` (7.832.0.1), for example:

```
auto i = 1, j = 2.0; // error: deduced types for i and j do not match
```

as opposed to

```
auto i = 1; // OK: i deduced to have type int
auto j = 2.0; // OK: j deduced to have type double
```

noptr-declarator:
  declarator-id attribute-specifier-seq$_{opt}$
  noptr-declarator parameters-and-qualifiers
  noptr-declarator `[` *constant-expression*$_{opt}$`]` *attribute-specifier-seq*$_{opt}$
  `(` *ptr-declarator* `)`

parameters-and-qualifiers:
  `(` *parameter-declaration-clause* `)` *cv-qualifier-seq*$_{opt}$
    ref-qualifier$_{opt}$ *exception-specification*$_{opt}$ *attribute-specifier-seq*$_{opt}$

trailing-return-type:
  `->` *trailing-type-specifier-seq abstract-declarator*$_{opt}$

ptr-operator:
  `*` *attribute-specifier-seq*$_{opt}$ *cv-qualifier-seq*$_{opt}$
  `&` *attribute-specifier-seq*$_{opt}$
  `&&` *attribute-specifier-seq*$_{opt}$
  nested-name-specifier `*` *attribute-specifier-seq*$_{opt}$ *cv-qualifier-seq*$_{opt}$

cv-qualifier-seq:
  cv-qualifier cv-qualifier-seq$_{opt}$

cv-qualifier:
  `const`
  `volatile`

ref-qualifier:
  `&`
  `&&`

declarator-id:
  `...`$_{opt}$ *id-expression*

1

The optional *attribute-specifier-seq* in a *trailing-return-type* appertains to the indicated return type. The *type-id* in a *trailing-return-type* includes the longest possible sequence of *abstract-declarator*s. [*Note:* This resolves the ambiguous binding of array and function declarators. [*Example:*

```
auto f()->int(*)[4];   // function returning a pointer to array[4] of int
                       // not function returning array[4] of pointer to int
```

— *end example*] — *end note*]

8.32 Type names [dcl.name]

1

To specify type conversions explicitly, and as an argument of `sizeof`, `alignof`, `new`, or `typeid`, the name of a type shall be specified. This can be done with a *type-id*, which is syntactically a declaration for a variable or function of that type that omits the name of the entity.

type-id:
  type-specifier-seq abstract-declarator$_{opt}$

abstract-declarator:
  ptr-abstract-declarator
  noptr-abstract-declarator$_{opt}$ *parameters-and-qualifiers trailing-return-type*
  abstract-pack-declarator

ptr-abstract-declarator:
  noptr-abstract-declarator
  ptr-operator ptr-abstract-declarator$_{opt}$

noptr-abstract-declarator:
noptr-abstract-declarator$_{opt}$ *parameters-and-qualifiers*
noptr-abstract-declarator$_{opt}$ `[` *constant-expression*$_{opt}$ `]` *attribute-specifier-seq*$_{opt}$
`(` *ptr-abstract-declarator* `)`
abstract-pack-declarator:
noptr-abstract-pack-declarator
ptr-operator abstract-pack-declarator
noptr-abstract-pack-declarator:
noptr-abstract-pack-declarator parameters-and-qualifiers
noptr-abstract-pack-declarator `[` *constant-expression*$_{opt}$ `]` *attribute-specifier-seq*$_{opt}$
`...`

It is possible to identify uniquely the location in the *abstract-declarator* where the identifier would appear if the construction were a declarator in a declaration. The named type is then the same as the type of the hypothetical identifier. [*Example:*

```
int                 // int i
int *               // int *pi
int *[3]            // int *p[3]
int (*)[3]          // int (*p3i)[3]
int *()             // int *f()
int (*)(double)     // int (*pf)(double)
```

name respectively the types "`int`," "pointer to `int`," "array of 3 pointers to `int`," "pointer to array of 3 `int`," "function of (no parameters) returning pointer to `int`," and "pointer to a function of (`double`) returning `int`." — *end example*]

1 A type can also be named (often more easily) by using a *typedef* (7.235.1).

8.38 Ambiguity resolution [dcl.ambig.res]

1

The ambiguity arising from the similarity between a function-style cast and a declaration mentioned in 6.556 can also occur in the context of a declaration. In that context, the choice is between a function declaration with a redundant set of parentheses around a parameter name and an object declaration with a function-style cast as the initializer. Just as for the ambiguities mentioned in 6.556, the resolution is to consider any construct that could possibly be a declaration a declaration. [*Note:* A declaration can be explicitly disambiguated by a nonfunction-style cast, by an `=` to indicate initialization or by removing the redundant parentheses around the parameter name. — *end note*] [*Example:*

```
struct S {
  S(int);
};

void foo(double a) {
  S w(int(a));       // function declaration
  S x(int());        // function declaration
  S y((int)a);       // object declaration
  S z = int(a);      // object declaration
}
```

— *end example*]

1

The ambiguity arising from the similarity between a function-style cast and a *type-id* can occur in different contexts. The ambiguity appears as a choice between a function-style cast expression and a declaration of a

type. The resolution is that any construct that could possibly be a *type-id* in its syntactic context shall be considered a *type-id*.

1 [*Example:*

```
#include <cstddef>
char* p;
void* operator new(std::size_t, int);
void foo()  {
  const int x = 63;
  new (int(*p)) int;            // new-placement expression
  new (int(*[x]));              // new type-id
}
```

2 For another example,

```
template <class T>
struct S {
  T* p;
};
S<int()> x;                     // type-id
S<int(1)> y;                    // expression (ill-formed)
```

3 For another example,

```
void foo() {
  sizeof(int(1));               // expression
  sizeof(int());                // type-id (ill-formed)
}
```

4 For another example,

```
void foo() {
  (int(1));                     // expression
  (int())1;                     // type-id (ill-formed)
}
```

— *end example*]

5

Another ambiguity arises in a *parameter-declaration-clause* of a function declaration, or in a *type-id* that is the operand of a `sizeof` or `typeid` operator, when a *type-name* is nested in parentheses. In this case, the choice is between the declaration of a parameter of type pointer to function and the declaration of a parameter with redundant parentheses around the *declarator-id*. The resolution is to consider the *type-name* as a *simple-type-specifier* rather than a *declarator-id*. [*Example:*

```
class C { };
void f(int(C)) { }              // void f(int(*fp)(C c)) { }
                                // not: void f(int C);

int g(C);

void foo() {
  f(1);                         // error: cannot convert 1 to function pointer
  f(g);                         // OK
}
```

For another example,

```
class C { };
void h(int *(C[10]));          // void h(int *(*_fp)(C _parm[10]));
                               // not: void h(int *C[10]);
```

— *end example*]

8.56 Meaning of declarators [dcl.meaning]

1

A list of declarators appears after an optional (Clause 7) *decl-specifier-seq* (7.40). Each declarator contains exactly one *declarator-id*; it names the identifier that is declared. An *unqualified-id* occurring in a *declarator-id* shall be a simple *identifier* except for the declaration of some special functions (12.30, 12.659, 12.807, 13.1122) and for the declaration of template specializations or partial specializations (14.1614). When the *declarator-id* is qualified, the declaration shall refer to a previously declared member of the class or namespace to which the qualifier refers (or, in the case of a namespace, of an element of the inline namespace set of that namespace (7.1149.1)) or to a specialization thereof; the member shall not merely have been introduced by a *using-declaration* in the scope of the class or namespace nominated by the *nested-name-specifier* of the *declarator-id*. The *nested-name-specifier* of a qualified *declarator-id* shall not begin with a *decltype-specifier*. [*Note:* If the qualifier is the global `::` scope resolution operator, the *declarator-id* refers to a name declared in the global namespace scope. — *end note*] The optional *attribute-specifier-seq* following a *declarator-id* appertains to the entity that is declared.

1 A `static`, `thread_local`, `extern`, `register`, `mutable`, `friend`, `inline`, `virtual`, or `typedef` specifier applies directly to each *declarator-id* in an *init-declarator-list*; the type specified for each *declarator-id* depends on both the *decl-specifier-seq* and its *declarator*.

2

Thus, a declaration of a particular identifier has the form

```
T D
```

where `T` is of the form *attribute-specifier-seq*$_{opt}$ *decl-specifier-seq* and `D` is a declarator. Following is a recursive procedure for determining the type specified for the contained *declarator-id* by such a declaration.

1 First, the *decl-specifier-seq* determines a type. In a declaration

```
T D
```

the *decl-specifier-seq* `T` determines the type `T`. [*Example:* in the declaration

```
int unsigned i;
```

the type specifiers `int unsigned` determine the type "`unsigned int`" (7.678.0.1). — *end example*]

2 In a declaration *attribute-specifier-seq*$_{opt}$ `T D` where `D` is an unadorned identifier the type of this identifier is "`T`".

3

In a declaration `T D` where `D` has the form

(D1)

the type of the contained *declarator-id* is the same as that of the contained *declarator-id* in the declaration

```
T D1
```

Parentheses do not alter the type of the embedded *declarator-id*, but they can alter the binding of complex declarators.

8.94.1 Pointers [dcl.ptr]

1

In a declaration `T D` where `D` has the form

`*` *attribute-specifier-seq*$_{opt}$ *cv-qualifier-seq*$_{opt}$`D1`

and the type of the identifier in the declaration `T D1` is "*derived-declarator-type-list* `T`," then the type of the identifier of `D` is "*derived-declarator-type-list cv-qualifier-seq* pointer to `T`." The *cv-qualifier*s apply to the pointer and not to the object pointed to. Similarly, the optional *attribute-specifier-seq* (7.1546.1) appertains to the pointer and not to the object pointed to.

1 [*Example:* the declarations

```
const int ci = 10, *pc = &ci, *const cpc = pc, **ppc;
int i, *p, *const cp = &i;
```

declare `ci`, a constant integer; `pc`, a pointer to a constant integer; `cpc`, a constant pointer to a constant integer; `ppc`, a pointer to a pointer to a constant integer; `i`, an integer; `p`, a pointer to integer; and `cp`, a constant pointer to integer. The value of `ci`, `cpc`, and `cp` cannot be changed after initialization. The value of `pc` can be changed, and so can the object pointed to by `cp`. Examples of some correct operations are

```
i = ci;
*cp = ci;
pc++;
pc = cpc;
pc = p;
ppc = &pc;
```

Examples of ill-formed operations are

```
ci = 1;          // error
ci++;            // error
*pc = 2;         // error
cp = &ci;        // error
cpc++;           // error
p = pc;          // error
ppc = &p;        // error
```

Each is unacceptable because it would either change the value of an object declared `const` or allow it to be changed through a cv-unqualified pointer later, for example:

```
*ppc = &ci;      // OK, but would make p point to ci ...
                 // ... because of previous error
*p = 5;          // clobber ci
```

— *end example*]

2 See also 5.3483 and 8.821.

3

[*Note:* Forming a pointer to reference type is ill-formed; see 8.97.1. Forming a pointer to function type is ill-formed if the function type has *cv-qualifier*s or a *ref-qualifier*; see 8.360.1. Since the address of a bit-field (9.921) cannot be taken, a pointer can never point to a bit-field. — *end note*]

8.97.1 References [dcl.ref]

1

In a declaration `T D` where `D` has either of the forms

& *attribute-specifier-seq*$_{opt}$D1
&& *attribute-specifier-seq*$_{opt}$D1

and the type of the identifier in the declaration `T D1` is "*derived-declarator-type-list* `T`," then the type of the identifier of `D` is "*derived-declarator-type-list* reference to `T`." The optional *attribute-specifier-seq* appertains to the reference type. Cv-qualified references are ill-formed except when the cv-qualifiers are introduced through the use of a *typedef-name* (7.235.1, 14.97) or *decltype-specifier* (7.678.0.1), in which case the cv-qualifiers are ignored. [*Example:*

```
typedef int& A;
const A aref = 3;    // ill-formed; lvalue reference to non-const initialized with rvalue
```

The type of `aref` is "lvalue reference to `int`", not "lvalue reference to `const int`". — *end example*] [*Note:* A reference can be thought of as a name of an object. — *end note*] A declarator that specifies the type "reference to *cv* `void`" is ill-formed.

1

A reference type that is declared using `&` is called an *lvalue reference*, and a reference type that is declared using `&&` is called an *rvalue reference*. Lvalue references and rvalue references are distinct types. Except where explicitly noted, they are semantically equivalent and commonly referred to as references.

1 [*Example:*

```
void f(double& a) { a += 3.14; }
// ...
double d = 0;
f(d);
```

declares `a` to be a reference parameter of `f` so the call `f(d)` will add `3.14` to `d`.

```
int v[20];
// ...
int& g(int i) { return v[i]; }
// ...
g(3) = 7;
```

declares the function `g()` to return a reference to an integer so `g(3)=7` will assign `7` to the fourth element of the array `v`. For another example,

```
struct link {
  link* next;
};

link* first;

void h(link*& p) {  // p is a reference to pointer
  p->next = first;
  first = p;
  p = 0;
}

void k() {
   link* q = new link;
   h(q);
}
```

declares `p` to be a reference to a pointer to `link` so `h(q)` will leave `q` with the value zero. See also 8.2156.1. — *end example*]

2

It is unspecified whether or not a reference requires storage (3.2235).

1

There shall be no references to references, no arrays of references, and no pointers to references. The declaration of a reference shall contain an *initializer* (8.2156.1) except when the declaration contains an explicit `extern` specifier (7.49.1), is a class member (9.194) declaration within a class definition, or is the declaration of a parameter or a return type (8.360.1); see 3.43. A reference shall be initialized to refer to a valid object or function. [*Note:* in particular, a null reference cannot exist in a well-defined program, because the only way to create such a reference would be to bind it to the "object" obtained by indirection through a null pointer, which causes undefined behavior. As described in 9.921, a reference cannot be bound directly to a bit-field. — *end note*]

1

If a *typedef-name* (7.235.1, 14.97) or a *decltype-specifier* (7.678.0.1) denotes a type `TR` that is a reference to a type `T`, an attempt to create the type "lvalue reference to *cv* `TR`" creates the type "lvalue reference to `T`", while an attempt to create the type "rvalue reference to *cv* `TR`" creates the type `TR`. [*Example:*

```
int i;
typedef int& LRI;
typedef int&& RRI;

LRI& r1 = i;                    // r1 has the type int&
const LRI& r2 = i;              // r2 has the type int&
const LRI&& r3 = i;             // r3 has the type int&

RRI& r4 = i;                    // r4 has the type int&
RRI&& r5 = 5;                   // r5 has the type int&&

decltype(r2)& r6 = i;           // r6 has the type int&
decltype(r2)&& r7 = i;          // r7 has the type int&
```

— *end example*]

1 [*Note:* Forming a reference to function type is ill-formed if the function type has *cv-qualifier*s or a *ref-qualifier*; see 8.360.1. — *end note*]

8.236.1 Pointers to members [dcl.mptr]

1

In a declaration `T D` where `D` has the form

nested-name-specifier `*` *attribute-specifier-seq*$_{opt}$ *cv-qualifier-seq*$_{opt}$ *D1*

and the *nested-name-specifier* denotes a class, and the type of the identifier in the declaration `T D1` is "*derived-declarator-type-list* `T`", then the type of the identifier of `D` is "*derived-declarator-type-list cv-qualifier-seq* pointer to member of class *nested-name-specifier* of type `T`". The optional *attribute-specifier-seq* (7.1546.1) appertains to the pointer-to-member.

1 [*Example:*

```
struct X {
  void f(int);
  int a;
};
struct Y;
```

```
int X::* pmi = &X::a;
void (X::* pmf)(int) = &X::f;
double X::* pmd;
char Y::* pmc;
```

declares `pmi`, `pmf`, `pmd` and `pmc` to be a pointer to a member of `X` of type `int`, a pointer to a member of `X` of type `void(int)`, a pointer to a member of `X` of type `double` and a pointer to a member of `Y` of type `char` respectively. The declaration of `pmd` is well-formed even though `X` has no members of type `double`. Similarly, the declaration of `pmc` is well-formed even though `Y` is an incomplete type. `pmi` and `pmf` can be used like this:

```
X obj;
// ...
obj.*pmi = 7;        // assign 7 to an integer
                     // member of obj
(obj.*pmf)(7);       // call a function member of obj
                     // with the argument 7
```

— *end example*]

2

A pointer to member shall not point to a static member of a class (9.559), a member with reference type, or "*cv* `void`."

[*Note:* See also 5.1897 and 5.2832. The type "pointer to member" is distinct from the type "pointer", that is, a pointer to member is declared only by the pointer to member declarator syntax, and never by the pointer declarator syntax. There is no "reference-to-member" type in C++. — *end note*]

8.251.1 Arrays [dcl.array]

1

In a declaration `T D` where `D` has the form

`D1 [` *constant-expression*$_{opt}$`]` *attribute-specifier-seq*$_{opt}$

and the type of the identifier in the declaration `T D1` is "*derived-declarator-type-list* `T`", then the type of the identifier of `D` is an array type; if the type of the identifier of `D` contains the `auto` *type-specifier*, the program is ill-formed. `T` is called the array *element type*; this type shall not be a reference type, the (possibly cv-qualified) type `void`, a function type or an abstract class type. If the *constant-expression* (5.3643) is present, it shall be a converted constant expression of type `std::size_t` and its value shall be greater than zero. The constant expression specifies the *bound* of (number of elements in) the array. If the value of the constant expression is `N`, the array has `N` elements numbered `0` to `N-1`, and the type of the identifier of `D` is "*derived-declarator-type-list* array of `N T`". An object of array type contains a contiguously allocated non-empty set of `N` subobjects of type `T`. Except as noted below, if the constant expression is omitted, the type of the identifier of `D` is "*derived-declarator-type-list* array of unknown bound of `T`", an incomplete object type. The type "*derived-declarator-type-list* array of `N T`" is a different type from the type "*derived-declarator-type-list* array of unknown bound of `T`", see 3.2955. Any type of the form "*cv-qualifier-seq* array of `N T`" is adjusted to "array of `N` *cv-qualifier-seq* `T`", and similarly for "array of unknown bound of `T`". The optional *attribute-specifier-seq* appertains to the array. [*Example:*

```
typedef int A[5], AA[2][3];
typedef const A CA;          // type is "array of 5 const int"
typedef const AA CAA;        // type is "array of 2 array of 3 const int"
```

— *end example*] [*Note:* An "array of `N` *cv-qualifier-seq* `T`" has cv-qualified type; see 3.3640.1. — *end note*]

1

An array can be constructed from one of the fundamental types (except `void`), from a pointer, from a pointer to member, from a class, from an enumeration type, or from another array.

1

When several "array of" specifications are adjacent, a multidimensional array is created; only the first of the constant expressions that specify the bounds of the arrays may be omitted. In addition to declarations in which an incomplete object type is allowed, an array bound may be omitted in some cases in the declaration of a function parameter (8.360.1). An array bound may also be omitted when the declarator is followed by an *initializer* (8.821). In this case the bound is calculated from the number of initial elements (say, `N`) supplied (8.1817.1), and the type of the identifier of `D` is "array of `N` `T`." Furthermore, if there is a preceding declaration of the entity in the same scope in which the bound was specified, an omitted array bound is taken to be the same as in that earlier declaration, and similarly for the definition of a static data member of a class.

1 [*Example:*

```
float fa[17], *afp[17];
```

declares an array of `float` numbers and an array of pointers to `float` numbers. For another example,

```
static int x3d[3][5][7];
```

declares a static three-dimensional array of integers, with rank $3 \times 5 \times 7$. In complete detail, `x3d` is an array of three items; each item is an array of five arrays; each of the latter arrays is an array of seven integers. Any of the expressions `x3d`, `x3d[i]`, `x3d[i][j]`, `x3d[i][j][k]` can reasonably appear in an expression. Finally,

```
extern int x[10];
struct S {
  static int y[10];
};

int x[];                    // OK: bound is 10
int S::y[];                 // OK: bound is 10

void f() {
  extern int x[];
  int i = sizeof(x);        // error: incomplete object type
}
```

— *end example*]

2

[*Note:* conversions affecting expressions of array type are described in 4.180. Objects of array types cannot be modified, see 3.3673. — *end note*]

1

[*Note:* Except where it has been declared for a class (13.1210.1), the subscript operator `[]` is interpreted in such a way that `E1[E2]` is identical to `*((E1)+(E2))`. Because of the conversion rules that apply to `+`, if `E1` is an array and `E2` an integer, then `E1[E2]` refers to the `E2`-th member of `E1`. Therefore, despite its asymmetric appearance, subscripting is a commutative operation.

1

A consistent rule is followed for multidimensional arrays. If `E` is an n-dimensional array of rank $i \times j \times \ldots \times k$, then `E` appearing in an expression that is subject to the array-to-pointer conversion (4.180) is converted to a pointer to an $(n-1)$-dimensional array with rank $j \times \ldots \times k$. If the `*` operator, either explicitly or implicitly

as a result of subscripting, is applied to this pointer, the result is the pointed-to $(n-1)$-dimensional array, which itself is immediately converted into a pointer.

1

[*Example:* consider

```
int x[3][5];
```

Here `x` is a 3×5 array of integers. When `x` appears in an expression, it is converted to a pointer to (the first of three) five-membered arrays of integers. In the expression `x[i]` which is equivalent to `*(x+i)`, `x` is first converted to a pointer as described; then `x+i` is converted to the type of `x`, which involves multiplying `i` by the length of the object to which the pointer points, namely five integer objects. The results are added and indirection applied to yield an array (of five integers), which in turn is converted to a pointer to the first of the integers. If there is another subscript the same argument applies again; this time the result is an integer. — *end example*] — *end note*]

1

[*Note:* It follows from all this that arrays in C++ are stored row-wise (last subscript varies fastest) and that the first subscript in the declaration helps determine the amount of storage consumed by an array but plays no other part in subscript calculations. — *end note*]

8.360.1 Functions [dcl.fct]

1

In a declaration `T D` where `D` has the form

`D1 (` *parameter-declaration-clause* `)` *cv-qualifier-seq*$_{opt}$
ref-qualifier$_{opt}$ *exception-specification*$_{opt}$ *attribute-specifier-seq*$_{opt}$

and the type of the contained *declarator-id* in the declaration `T D1` is "*derived-declarator-type-list* `T`", the type of the *declarator-id* in `D` is "*derived-declarator-type-list* function of (*parameter-declaration-clause*) *cv-qualifier-seq*$_{opt}$ *ref-qualifier*$_{opt}$ returning `T`". The optional *attribute-specifier-seq* appertains to the function type.

1

In a declaration `T D` where `D` has the form

`D1 (` *parameter-declaration-clause* `)` *cv-qualifier-seq*$_{opt}$
ref-qualifier$_{opt}$ *exception-specification*$_{opt}$ *attribute-specifier-seq*$_{opt}$ *trailing-return-type*

and the type of the contained *declarator-id* in the declaration `T D1` is "*derived-declarator-type-list* `T`", `T` shall be the single *type-specifier* `auto`. The type of the *declarator-id* in `D` is "*derived-declarator-type-list* function of (*parameter-declaration-clause*) *cv-qualifier-seq*$_{opt}$ *ref-qualifier*$_{opt}$ returning *trailing-return-type*". The optional *attribute-specifier-seq* appertains to the function type.

1

A type of either form is a *function type*.[100]

parameter-declaration-clause:
parameter-declaration-list$_{opt}$ ...$_{opt}$
parameter-declaration-list `,` ...

parameter-declaration-list:
parameter-declaration
parameter-declaration-list `,` *parameter-declaration*

100) As indicated by syntax, cv-qualifiers are a significant component in function return types.

parameter-declaration:
attribute-specifier-seq$_{opt}$ *decl-specifier-seq declarator*
attribute-specifier-seq$_{opt}$ *decl-specifier-seq declarator* `=` *initializer-clause*
attribute-specifier-seq$_{opt}$ *decl-specifier-seq abstract-declarator*$_{opt}$
attribute-specifier-seq$_{opt}$ *decl-specifier-seq abstract-declarator*$_{opt}$`=` *initializer-clause*

The optional *attribute-specifier-seq* in a *parameter-declaration* appertains to the parameter.

1

The *parameter-declaration-clause* determines the arguments that can be specified, and their processing, when the function is called. [*Note:* the *parameter-declaration-clause* is used to convert the arguments specified on the function call; see 5.955.1. — *end note*] If the *parameter-declaration-clause* is empty, the function takes no arguments. A parameter list consisting of a single unnamed parameter of non-dependent type `void` is equivalent to an empty parameter list. Except for this special case, a parameter shall not have type *cv* `void`. If the *parameter-declaration-clause* terminates with an ellipsis or a function parameter pack (14.703.1), the number of arguments shall be equal to or greater than the number of parameters that do not have a default argument and are not function parameter packs. Where syntactically correct and where "*...*" is not part of an *abstract-declarator*, "*, ...*" is synonymous with "*...*". [*Example:* the declaration

```
int printf(const char*, ...);
```

declares a function that can be called with varying numbers and types of arguments.

```
printf("hello world");
printf("a=%d b=%d", a, b);
```

However, the first argument must be of a type that can be converted to a `const char*` — *end example*] [*Note:* The standard header `<cstdarg>` contains a mechanism for accessing arguments passed using the ellipsis (see 5.955.1 and 18.295). — *end note*]

1

A single name can be used for several different functions in a single scope; this is function overloading (Clause 13). All declarations for a function shall agree exactly in both the return type and the parameter-type-list. The type of a function is determined using the following rules. The type of each parameter (including function parameter packs) is determined from its own *decl-specifier-seq* and *declarator*. After determining the type of each parameter, any parameter of type "array of `T`" or "function returning `T`" is adjusted to be "pointer to `T`" or "pointer to function returning `T`," respectively. After producing the list of parameter types, any top-level *cv-qualifier*s modifying a parameter type are deleted when forming the function type. The resulting list of transformed parameter types and the presence or absence of the ellipsis or a function parameter pack is the function's *parameter-type-list*. [*Note:* This transformation does not affect the types of the parameters. For example, `int(*)(const int p, decltype(p)*)` and `int(*)(int, const int*)` are identical types. — *end note*]

1

A function type with a *cv-qualifier-seq* or a *ref-qualifier* (including a type named by *typedef-name* (7.235.1, 14.97)) shall appear only as:

— the function type for a non-static member function,

— the function type to which a pointer to member refers,

— the top-level function type of a function typedef declaration or *alias-declaration*,

— the *type-id* in the default argument of a *type-parameter* (14.97), or

— the *type-id* of a *template-argument* for a *type-parameter* (14.349.1).

[*Example:*

```
typedef int FIC(int) const;
FIC f;                // ill-formed: does not declare a member function
struct S {
  FIC f;              // OK
};
FIC S::*pm = &S::f;   // OK
```

— *end example*]

The effect of a *cv-qualifier-seq* in a function declarator is not the same as adding cv-qualification on top of the function type. In the latter case, the cv-qualifiers are ignored. [*Note:* a function type that has a *cv-qualifier-seq* is not a cv-qualified type; there are no cv-qualified function types. — *end note*] [*Example:*

```
typedef void F();
struct S {
  const F f;          // OK: equivalent to: void f();
};
```

— *end example*] The return type, the parameter-type-list, the *ref-qualifier*, and the *cv-qualifier-seq*, but not the default arguments (8.545.1) or the exception specification (15.228), are part of the function type. [*Note:* Function types are checked during the assignments and initializations of pointers to functions, references to functions, and pointers to member functions. — *end note*]

1 [*Example:* the declaration

```
int fseek(FILE*, long, int);
```

declares a function taking three arguments of the specified types, and returning `int` (7.519.1). — *end example*]

2

If the type of a parameter includes a type of the form "pointer to array of unknown bound of `T`" or "reference to array of unknown bound of `T`," the program is ill-formed.[101] Functions shall not have a return type of type array or function, although they may have a return type of type pointer or reference to such things. There shall be no arrays of functions, although there can be arrays of pointers to functions.

1

Types shall not be defined in return or parameter types. The type of a parameter or the return type for a function definition shall not be an incomplete class type (possibly cv-qualified) unless the function is deleted (8.793.1) or the definition is nested within the *member-specification* for that class (including definitions in nested classes defined within the class).

1

A typedef of function type may be used to declare a function but shall not be used to define a function (8.706). [*Example:*

```
typedef void F();
F  fv;                // OK: equivalent to void fv();
F  fv { }             // ill-formed
void fv() { }         // OK: definition of fv
```

— *end example*]

101) This excludes parameters of type "*ptr-arr-seq* `T2`" where `T2` is "pointer to array of unknown bound of `T`" and where *ptr-arr-seq* means any sequence of "pointer to" and "array of" derived declarator types. This exclusion applies to the parameters of the function, and if a parameter is a pointer to function or pointer to member function then to its parameters also, etc.

1

An identifier can optionally be provided as a parameter name; if present in a function definition (8.706), it names a parameter. [*Note:* In particular, parameter names are also optional in function definitions and names used for a parameter in different declarations and the definition of a function need not be the same. If a parameter name is present in a function declaration that is not a definition, it cannot be used outside of its function declarator because that is the extent of its potential scope (3.729.1). — *end note*]

1

[*Example:* the declaration

```
int i,
    *pi,
    f(),
    *fpi(int),
    (*pif)(const char*, const char*),
    (*fpif(int))(int);
```

declares an integer `i`, a pointer `pi` to an integer, a function `f` taking no arguments and returning an integer, a function `fpi` taking an integer argument and returning a pointer to an integer, a pointer `pif` to a function which takes two pointers to constant characters and returns an integer, a function `fpif` taking an integer argument and returning a pointer to a function that takes an integer argument and returns an integer. It is especially useful to compare `fpi` and `pif`. The binding of `*fpi(int)` is `*(fpi(int))`, so the declaration suggests, and the same construction in an expression requires, the calling of a function `fpi`, and then using indirection through the (pointer) result to yield an integer. In the declarator `(*pif)(const char*, const char*)`, the extra parentheses are necessary to indicate that indirection through a pointer to a function yields a function, which is then called. — *end example*] [*Note:* Typedefs and *trailing-return-type*s are sometimes convenient when the return type of a function is complex. For example, the function `fpif` above could have been declared

```
typedef int  IFUNC(int);
IFUNC*  fpif(int);
```

or

```
auto fpif(int)->int(*)(int);
```

A *trailing-return-type* is most useful for a type that would be more complicated to specify before the *declarator-id*:

```
template <class T, class U> auto add(T t, U u) -> decltype(t + u);
```

rather than

```
template <class T, class U> decltype((*(T*)0) + (*(U*)0)) add(T t, U u);
```

— *end note*]

1 A *non-template function* is a function that is not a function template specialization. [*Note:* A function template is not a function. — *end note*]

2 A *declarator-id* or *abstract-declarator* containing an ellipsis shall only be used in a *parameter-declaration*. Such a *parameter-declaration* is a parameter pack (14.703.1). When it is part of a *parameter-declaration-clause*, the parameter pack is a function parameter pack (14.703.1). [*Note:* Otherwise, the *parameter-declaration* is part of a *template-parameter-list* and the parameter pack is a template parameter pack; see 14.97. — *end note*] A function parameter pack is a pack expansion (14.703.1). [*Example:*

```
template<typename... T> void f(T (* ...t)(int, int));
```

```
int add(int, int);
float subtract(int, int);

void g() {
  f(add, subtract);
}
```

— *end example*]

3 There is a syntactic ambiguity when an ellipsis occurs at the end of a *parameter-declaration-clause* without a preceding comma. In this case, the ellipsis is parsed as part of the *abstract-declarator* if the type of the parameter either names a template parameter pack that has not been expanded or contains `auto`; otherwise, it is parsed as part of the *parameter-declaration-clause*.[102]

8.545.1 Default arguments [dcl.fct.default]

1

If an *initializer-clause* is specified in a *parameter-declaration* this *initializer-clause* is used as a default argument. Default arguments will be used in calls where trailing arguments are missing.

1

[*Example:* the declaration

```
void point(int = 3, int = 4);
```

declares a function that can be called with zero, one, or two arguments of type `int`. It can be called in any of these ways:

```
point(1,2);  point(1);  point();
```

The last two calls are equivalent to `point(1,4)` and `point(3,4)`, respectively. — *end example*]

1

A default argument shall be specified only in the *parameter-declaration-clause* of a function declaration or in a *template-parameter* (14.97); in the latter case, the *initializer-clause* shall be an *assignment-expression*. A default argument shall not be specified for a parameter pack. If it is specified in a *parameter-declaration-clause*, it shall not occur within a *declarator* or *abstract-declarator* of a *parameter-declaration*.[103]

1

For non-template functions, default arguments can be added in later declarations of a function in the same scope. Declarations in different scopes have completely distinct sets of default arguments. That is, declarations in inner scopes do not acquire default arguments from declarations in outer scopes, and vice versa. In a given function declaration, each parameter subsequent to a parameter with a default argument shall have a default argument supplied in this or a previous declaration or shall be a function parameter pack. A default argument shall not be redefined by a later declaration (not even to the same value). [*Example:*

```
void g(int = 0, ...);          // OK, ellipsis is not a parameter so it can follow
                               // a parameter with a default argument
void f(int, int);
void f(int, int = 7);
```

102) One can explicitly disambiguate the parse either by introducing a comma (so the ellipsis will be parsed as part of the *parameter-declaration-clause*) or by introducing a name for the parameter (so the ellipsis will be parsed as part of the *declarator-id*).

103) This means that default arguments cannot appear, for example, in declarations of pointers to functions, references to functions, or `typedef` declarations.

```
void h() {
  f(3);                          // OK, calls f(3, 7)
  void f(int = 1, int);          // error: does not use default
                                 // from surrounding scope
}
void m() {
  void f(int, int);              // has no defaults
  f(4);                          // error: wrong number of arguments
  void f(int, int = 5);          // OK
  f(4);                          // OK, calls f(4, 5);
  void f(int, int = 5);          // error: cannot redefine, even to
                                 // same value
}
void n() {
  f(6);                          // OK, calls f(6, 7)
}
```

— *end example*] For a given inline function defined in different translation units, the accumulated sets of default arguments at the end of the translation units shall be the same; see 3.91. If a friend declaration specifies a default argument expression, that declaration shall be a definition and shall be the only declaration of the function or function template in the translation unit.

1

The default argument has the same semantic constraints as the initializer in a declaration of a variable of the parameter type, using the copy-initialization semantics (8.821). The names in the default argument are bound, and the semantic constraints are checked, at the point where the default argument appears. Name lookup and checking of semantic constraints for default arguments in function templates and in member functions of class templates are performed as described in 14.1644.1. [*Example:* in the following code, `g` will be called with the value `f(2)`:

```
int a = 1;
int f(int);
int g(int x = f(a));             // default argument: f(::a)

void h() {
  a = 2;
  {
  int a = 3;
  g();                           // g(f(::a))
  }
}
```

— *end example*] [*Note:* In member function declarations, names in default arguments are looked up as described in 3.952.1. Access checking applies to names in default arguments as described in Clause 11. — *end note*]

1

Except for member functions of class templates, the default arguments in a member function definition that appears outside of the class definition are added to the set of default arguments provided by the member function declaration in the class definition; the program is ill-formed if a default constructor (12.30), copy or move constructor, or copy or move assignment operator (12.1577) is so declared. Default arguments for a member function of a class template shall be specified on the initial declaration of the member function within the class template. [*Example:*

```
class C {
```

```
  void f(int i = 3);
  void g(int i, int j = 99);
};

void C::f(int i = 3) {          // error: default argument already
}                               // specified in class scope
void C::g(int i = 88, int j) {  // in this translation unit,
}                               // C::g can be called with no argument
```

— *end example*]

1

Local variables shall not be used in a default argument. [*Example:*

```
void f() {
  int i;
  extern void g(int x = i);     //error
  // ...
}
```

— *end example*]

1

The keyword `this` shall not be used in a default argument of a member function. [*Example:*

```
class A {
  void f(A* p = this) { }       // error
};
```

— *end example*]

1

A default argument is evaluated each time the function is called with no argument for the corresponding parameter. The order of evaluation of function arguments is unspecified. Consequently, parameters of a function shall not be used in a default argument, even if they are not evaluated. Parameters of a function declared before a default argument are in scope and can hide namespace and class member names. [*Example:*

```
int a;
int f(int a, int b = a);            // error: parameter a
                                    // used as default argument
typedef int I;
int g(float I, int b = I(2));       // error: parameter I found
int h(int a, int b = sizeof(a));    // error, parameter a used
                                    // in default argument
```

— *end example*] Similarly, a non-static member shall not be used in a default argument, even if it is not evaluated, unless it appears as the *id-expression* of a class member access expression (5.1194.1) or unless it is used to form a pointer to member (5.1898.1). [*Example:* the declaration of `X::mem1()` in the following example is ill-formed because no object is supplied for the non-static member `X::a` used as an initializer.

```
int b;
class X {
  int a;
  int mem1(int i = a);          // error: non-static member a
                                // used as default argument
  int mem2(int i = b);          // OK; use X::b
  static int b;
```

```
};
```

The declaration of `X::mem2()` is meaningful, however, since no object is needed to access the static member `X::b`. Classes, objects, and members are described in Clause 9. — *end example*] A default argument is not part of the type of a function. [*Example:*

```
int f(int = 0);

void h() {
  int j = f(1);
  int k = f();                    // OK, means f(0)
}

int (*p1)(int) = &f;
int (*p2)() = &f;                 // error: type mismatch
```

— *end example*] When a declaration of a function is introduced by way of a *using-declaration* (7.1311.1), any default argument information associated with the declaration is made known as well. If the function is redeclared thereafter in the namespace with additional default arguments, the additional arguments are also known at any point following the redeclaration where the *using-declaration* is in scope.

1

A virtual function call (10.113) uses the default arguments in the declaration of the virtual function determined by the static type of the pointer or reference denoting the object. An overriding function in a derived class does not acquire default arguments from the function it overrides. [*Example:*

```
struct A {
  virtual void f(int a = 7);
};
struct B : public A {
  void f(int a);
};
void m() {
  B* pb = new B;
  A* pa = pb;
  pa->f();            // OK, calls pa->B::f(7)
  pb->f();            // error: wrong number of arguments for B::f()
}
```

— *end example*]

8.706 Function definitions [dcl.fct.def]

8.706.1 In general [dcl.fct.def.general]

1

Function definitions have the form

function-definition:
  attribute-specifier-seq$_{opt}$ *decl-specifier-seq*$_{opt}$ *declarator virt-specifier-seq*$_{opt}$ *function-body*

function-body:
  ctor-initializer$_{opt}$ *compound-statement*
  function-try-block
  `= default ;`
  `= delete ;`

Any informal reference to the body of a function should be interpreted as a reference to the non-terminal *function-body*. The optional *attribute-specifier-seq* in a *function-definition* appertains to the function. A *virt-specifier-seq* can be part of a *function-definition* only if it is a *member-declaration* (9.194).

1

The *declarator* in a *function-definition* shall have the form

`D1 (` *parameter-declaration-clause* `)` *cv-qualifier-seq*$_{opt}$ *ref-qualifier*$_{opt}$ *exception-specification*$_{opt}$ *attribute-specifier-seq*$_{opt}$ *trailing-return-type*$_{opt}$

as described in 8.360.1. A function shall be defined only in namespace or class scope.

1 [*Example:* a simple example of a complete function definition is

```
int max(int a, int b, int c) {
  int m = (a > b) ? a : b;
  return (m > c) ? m : c;
}
```

Here `int` is the *decl-specifier-seq*; `max(int a, int b, int c)` is the *declarator*; `{ /* ... */ }` is the *function-body*. — *end example*]

2 A *ctor-initializer* is used only in a constructor; see 12.30 and 12.1011.

3

A *cv-qualifier-seq* or a *ref-qualifier* (or both) can be part of a non-static member function declaration, non-static member function definition, or pointer to member function only (8.360.1); see 9.508.1.

1

[*Note:* Unused parameters need not be named. For example,

```
void print(int a, int) {
  std::printf("a = %d\n",a);
}
```

— *end note*]

1 In the *function-body*, a *function-local predefined variable* denotes a block-scope object of static storage duration that is implicitly defined (see 3.694.1).

2

The function-local predefined variable `__func__` is defined as if a definition of the form

```
static const char __func__[] = "function-name";
```

had been provided, where *function-name* is an implementation-defined string. It is unspecified whether such a variable has an address distinct from that of any other object in the program.[104]

[*Example:*

```
struct S {
  S() : s(__func__) { }          // OK
  const char* s;
};
void f(const char* s = __func__);  // error: __func__ is undeclared
```

— *end example*]

104) Implementations are permitted to provide additional predefined variables with names that are reserved to the implementation (17.332.0.0.1). If a predefined variable is not odr-used (3.91), its string value need not be present in the program image.

8.730.1 Explicitly-defaulted functions [dcl.fct.def.default]

1

A function definition of the form:

attribute-specifier-seq$_{opt}$ *decl-specifier-seq*$_{opt}$ *declarator virt-specifier-seq*$_{opt}$ `= default ;`

is called an *explicitly-defaulted* definition. A function that is explicitly defaulted shall

— be a special member function,

— have the same declared function type (except for possibly differing *ref-qualifier*s and except that in the case of a copy constructor or copy assignment operator, the parameter type may be "reference to non-const `T`", where `T` is the name of the member function's class) as if it had been implicitly declared, and

— not have default arguments.

1

An explicitly-defaulted function may be declared `constexpr` only if it would have been implicitly declared as `constexpr`. If a function is explicitly defaulted on its first declaration,

— it is implicitly considered to be `constexpr` if the implicit declaration would be, and,

— it is implicitly considered to have the same *exception-specification* as if it had been implicitly declared (15.228).

1

If a function that is explicitly defaulted has an explicit *exception-specification* that is not compatible (15.228) with the *exception-specification* on the implicit declaration, then

— if the function is explicitly defaulted on its first declaration, it is defined as deleted;

— otherwise, the program is ill-formed.

1 [*Example:*

```
struct S {
  constexpr S() = default;                  // ill-formed: implicit S() is not constexpr
  S(int a = 0) = default;                   // ill-formed: default argument
  void operator=(const S&) = default;       // ill-formed: non-matching return type
  ~S() throw(int) = default;                // deleted: exception specification does not match
private:
  int i;
  S(S&);                                    // OK: private copy constructor
};
S::S(S&) = default;                         // OK: defines copy constructor
```

— *end example*]

2

Explicitly-defaulted functions and implicitly-declared functions are collectively called *defaulted* functions, and the implementation shall provide implicit definitions for them (12.30 12.807, 12.1577), which might mean defining them as deleted. A function is *user-provided* if it is user-declared and not explicitly defaulted or deleted on its first declaration. A user-provided explicitly-defaulted function (i.e., explicitly defaulted after its first declaration) is defined at the point where it is explicitly defaulted; if such a function is implicitly defined as deleted, the program is ill-formed. [*Note:* Declaring a function as defaulted after its

first declaration can provide efficient execution and concise definition while enabling a stable binary interface to an evolving code base. — *end note*]

1 [*Example:*

```
struct trivial {
  trivial() = default;
  trivial(const trivial&) = default;
  trivial(trivial&&) = default;
  trivial& operator=(const trivial&) = default;
  trivial& operator=(trivial&&) = default;
  ~trivial() = default;
};

struct nontrivial1 {
  nontrivial1();
};
nontrivial1::nontrivial1() = default;          // not first declaration
```

— *end example*]

8.793.1 Deleted definitions [dcl.fct.def.delete]

1

A function definition of the form:

attribute-specifier-seq$_{opt}$ *decl-specifier-seq*$_{opt}$ *declarator virt-specifier-seq*$_{opt}$ `= delete ;`

is called a *deleted definition*. A function with a deleted definition is also called a *deleted function*.

1

A program that refers to a deleted function implicitly or explicitly, other than to declare it, is ill-formed. [*Note:* This includes calling the function implicitly or explicitly and forming a pointer or pointer-to-member to the function. It applies even for references in expressions that are not potentially-evaluated. If a function is overloaded, it is referenced only if the function is selected by overload resolution. — *end note*]

1

[*Example:* One can enforce non-default initialization and non-integral initialization with

```
struct onlydouble {
  onlydouble() = delete;              // OK, but redundant
  onlydouble(std::intmax_t) = delete;
  onlydouble(double);
};
```

— *end example*]

[*Example:* One can prevent use of a class in certain `new` expressions by using deleted definitions of a user-declared `operator new` for that class.

```
struct sometype {
  void* operator new(std::size_t) = delete;
  void* operator new[](std::size_t) = delete;
};
sometype* p = new sometype;     // error, deleted class operator new
sometype* q = new sometype[3];  // error, deleted class operator new[]
```

— *end example*]

[*Example:* One can make a class uncopyable, i.e. move-only, by using deleted definitions of the copy constructor and copy assignment operator, and then providing defaulted definitions of the move constructor and move assignment operator.

```
struct moveonly {
  moveonly() = default;
  moveonly(const moveonly&) = delete;
  moveonly(moveonly&&) = default;
  moveonly& operator=(const moveonly&) = delete;
  moveonly& operator=(moveonly&&) = default;
  ~moveonly() = default;
};
moveonly* p;
moveonly q(*p); // error, deleted copy constructor
```

— *end example*]

1

A deleted function is implicitly inline. [*Note:* The one-definition rule (3.91) applies to deleted definitions. — *end note*] A deleted definition of a function shall be the first declaration of the function or, for an explicit specialization of a function template, the first declaration of that specialization. [*Example:*

```
struct sometype {
  sometype();
};
sometype::sometype() = delete;        // ill-formed; not first declaration
```

— *end example*]

8.821 Initializers [dcl.init]

1

A declarator can specify an initial value for the identifier being declared. The identifier designates a variable being initialized. The process of initialization described in the remainder of 8.821 applies also to initializations specified by other syntactic contexts, such as the initialization of function parameters with argument expressions (5.955.1) or the initialization of return values (6.270.2).

initializer:
  brace-or-equal-initializer
  `(` *expression-list* `)`

brace-or-equal-initializer:
  `=` *initializer-clause*
  braced-init-list

initializer-clause:
  assignment-expression
  braced-init-list

initializer-list:
  initializer-clause `...`$_{opt}$
  initializer-list `,` *initializer-clause* `...`$_{opt}$

braced-init-list:
  `{` *initializer-list* `,`$_{opt}$ `}`
  `{ }`

1

Except for objects declared with the `constexpr` specifier, for which see 7.328.1, an *initializer* in the definition of a variable can consist of arbitrary expressions involving literals and previously declared variables and functions, regardless of the variable's storage duration. [*Example:*

```
int f(int);
int a = 2;
int b = f(a);
int c(b);
```

— *end example*]

1 [*Note:* Default arguments are more restricted; see 8.545.1.

2 The order of initialization of variables with static storage duration is described in 3.1721 and 6.419. — *end note*]

3

A declaration of a block-scope variable with external or internal linkage that has an *initializer* is ill-formed.

1

To *zero-initialize* an object or reference of type `T` means:

— if `T` is a scalar type (3.2955), the object is initialized to the value obtained by converting the integer literal `0` (zero) to `T`;[105]

— if `T` is a (possibly cv-qualified) non-union class type, each non-static data member and each base-class subobject is zero-initialized and padding is initialized to zero bits;

— if `T` is a (possibly cv-qualified) union type, the object's first non-static named data member is zero-initialized and padding is initialized to zero bits;

— if `T` is an array type, each element is zero-initialized;

— if `T` is a reference type, no initialization is performed.

1

To *default-initialize* an object of type `T` means:

— if `T` is a (possibly cv-qualified) class type (Clause 9), the default constructor (12.30) for `T` is called (and the initialization is ill-formed if `T` has no default constructor or overload resolution (13.88) results in an ambiguity or in a function that is deleted or inaccessible from the context of the initialization);

— if `T` is an array type, each element is default-initialized;

— otherwise, no initialization is performed.

If a program calls for the default initialization of an object of a const-qualified type `T`, `T` shall be a class type with a user-provided default constructor.

1

To *value-initialize* an object of type `T` means:

— if `T` is a (possibly cv-qualified) class type (Clause 9) with either no default constructor (12.30) or a default constructor that is user-provided or deleted, then the object is default-initialized;

— if `T` is a (possibly cv-qualified) class type without a user-provided or deleted default constructor, then the object is zero-initialized and the semantic constraints for default-initialization are checked, and if `T` has a non-trivial default constructor, the object is default-initialized;

105) As specified in 4.579, converting an integer literal whose value is `0` to a pointer type results in a null pointer value.

— if `T` is an array type, then each element is value-initialized;

— otherwise, the object is zero-initialized.

An object that is value-initialized is deemed to be constructed and thus subject to provisions of this International Standard applying to "constructed" objects, objects "for which the constructor has completed," etc., even if no constructor is invoked for the object's initialization.

1

A program that calls for default-initialization or value-initialization of an entity of reference type is ill-formed.

1

[*Note:* Every object of static storage duration is zero-initialized at program startup before any other initialization takes place. In some cases, additional initialization is done later. — *end note*]

1

An object whose initializer is an empty set of parentheses, i.e., `()`, shall be value-initialized.

[*Note:* Since `()` is not permitted by the syntax for *initializer*,

```
X a();
```

is not the declaration of an object of class `X`, but the declaration of a function taking no argument and returning an `X`. The form `()` is permitted in certain other initialization contexts (5.2221.1, 5.1108.1, 12.1026.1). — *end note*]

1

If no initializer is specified for an object, the object is default-initialized. When storage for an object with automatic or dynamic storage duration is obtained, the object has an *indeterminate value*, and if no initialization is performed for the object, that object retains an indeterminate value until that value is replaced (5.3483). [*Note:* Objects with static or thread storage duration are zero-initialized, see 3.1937.1. — *end note*] If an indeterminate value is produced by an evaluation, the behavior is undefined except in the following cases:

— If an indeterminate value of unsigned narrow character type (3.3151.1) is produced by the evaluation of:

  — the second or third operand of a conditional expression (5.3337),

  — the right operand of a comma expression (5.3602),

  — the operand of a cast or conversion to an unsigned narrow character type (4.397, 5.1108.1, 5.1443.1, 5.2765), or

  — a discarded-value expression (Clause 5),

  then the result of the operation is an indeterminate value.

— If an indeterminate value of unsigned narrow character type is produced by the evaluation of the right operand of a simple assignment operator (5.3483) whose first operand is an lvalue of unsigned narrow character type, an indeterminate value replaces the value of the object referred to by the left operand.

— If an indeterminate value of unsigned narrow character type is produced by the evaluation of the initialization expression when initializing an object of unsigned narrow character type, that object is initialized to an indeterminate value.

[*Example:*

```
int f(bool b) {
  unsigned char c;
  unsigned char d = c; // OK, d has an indeterminate value
  int e = d;           // undefined behavior
  return b ? d : 0;    // undefined behavior if b is true
}
```

— *end example*]

1

An initializer for a static member is in the scope of the member's class. [*Example:*

```
int a;

struct X {
  static int a;
  static int b;
};

int X::a = 1;
int X::b = a;       // X::b = X::a
```

— *end example*]

1

The form of initialization (using parentheses or `=`) is generally insignificant, but does matter when the initializer or the entity being initialized has a class type; see below. If the entity being initialized does not have class type, the *expression-list* in a parenthesized initializer shall be a single expression.

1

The initialization that occurs in the form

```
T x = a;
```

as well as in argument passing, function return, throwing an exception (15.7), handling an exception (15.146), and aggregate member initialization (8.1817.1) is called *copy-initialization*. [*Note:* Copy-initialization may invoke a move (12.1577). — *end note*]

1

The initialization that occurs in the forms

```
T x(a);
T x{a};
```

as well as in `new` expressions (5.2221.1), `static_cast` expressions (5.1443.1), functional notation type conversions (5.1108.1), and base and member initializers (12.1026.1) is called *direct-initialization*.

1

The semantics of initializers are as follows. The *destination type* is the type of the object or reference being initialized and the *source type* is the type of the initializer expression. If the initializer is not a single (possibly parenthesized) expression, the source type is not defined.

— If the initializer is a (non-parenthesized) *braced-init-list*, the object or reference is list-initialized (8.2435.1).

— If the destination type is a reference type, see 8.2156.1.

— If the destination type is an array of characters, an array of `char16_t`, an array of `char32_t`, or an array of `wchar_t`, and the initializer is a string literal, see 8.2115.1.

— If the initializer is `()`, the object is value-initialized.

— Otherwise, if the destination type is an array, the program is ill-formed.

— If the destination type is a (possibly cv-qualified) class type:

  — If the initialization is direct-initialization, or if it is copy-initialization where the cv-unqualified version of the source type is the same class as, or a derived class of, the class of the destination, constructors are considered. The applicable constructors are enumerated (13.354.0.1), and the best one is chosen through overload resolution (13.88). The constructor so selected is called to initialize the object, with the initializer expression or *expression-list* as its argument(s). If no constructor applies, or the overload resolution is ambiguous, the initialization is ill-formed.

  — Otherwise (i.e., for the remaining copy-initialization cases), user-defined conversion sequences that can convert from the source type to the destination type or (when a conversion function is used) to a derived class thereof are enumerated as described in 13.368.0.1, and the best one is chosen through overload resolution (13.88). If the conversion cannot be done or is ambiguous, the initialization is ill-formed. The function selected is called with the initializer expression as its argument; if the function is a constructor, the call initializes a temporary of the cv-unqualified version of the destination type. The temporary is a prvalue. The result of the call (which is the temporary for the constructor case) is then used to direct-initialize, according to the rules above, the object that is the destination of the copy-initialization. In certain cases, an implementation is permitted to eliminate the copying inherent in this direct-initialization by constructing the intermediate result directly into the object being initialized; see 12.306, 12.1577.

— Otherwise, if the source type is a (possibly cv-qualified) class type, conversion functions are considered. The applicable conversion functions are enumerated (13.396.0.1), and the best one is chosen through overload resolution (13.88). The user-defined conversion so selected is called to convert the initializer expression into the object being initialized. If the conversion cannot be done or is ambiguous, the initialization is ill-formed.

— Otherwise, the initial value of the object being initialized is the (possibly converted) value of the initializer expression. Standard conversions (Clause 4) will be used, if necessary, to convert the initializer expression to the cv-unqualified version of the destination type; no user-defined conversions are considered. If the conversion cannot be done, the initialization is ill-formed. [*Note:* An expression of type "*cv1* `T`" can initialize an object of type "*cv2* `T`" independently of the cv-qualifiers *cv1* and *cv2*.

```
int a;
const int b = a;
int c = b;
```

— *end note*]

1 An *initializer-clause* followed by an ellipsis is a pack expansion (14.703.1).

8.1817.1 Aggregates [dcl.init.aggr]

1

An *aggregate* is an array or a class (Clause 9) with no user-provided constructors (12.30), no private or protected non-static data members (Clause 11), no base classes (Clause 10), and no virtual functions (10.113).

1

When an aggregate is initialized by an initializer list, as specified in 8.2435.1, the elements of the initializer list are taken as initializers for the members of the aggregate, in increasing subscript or member order. Each

member is copy-initialized from the corresponding *initializer-clause*. If the *initializer-clause* is an expression and a narrowing conversion (8.2435.1) is required to convert the expression, the program is ill-formed. [*Note:* If an *initializer-clause* is itself an initializer list, the member is list-initialized, which will result in a recursive application of the rules in this section if the member is an aggregate. — *end note*] [*Example:*

```
struct A {
  int x;
  struct B {
    int i;
    int j;
  } b;
} a = { 1, { 2, 3 } };
```

initializes `a.x` with 1, `a.b.i` with 2, `a.b.j` with 3. — *end example*]

1

An aggregate that is a class can also be initialized with a single expression not enclosed in braces, as described in 8.821.

1

An array of unknown size initialized with a brace-enclosed *initializer-list* containing `n` *initializer-clause*s, where `n` shall be greater than zero, is defined as having `n` elements (8.251.1). [*Example:*

```
int x[] = { 1, 3, 5 };
```

declares and initializes `x` as a one-dimensional array that has three elements since no size was specified and there are three initializers. — *end example*] An empty initializer list `{}` shall not be used as the *initializer-clause* for an array of unknown bound.[106]

1

Static data members and anonymous bit-fields are not considered members of the class for purposes of aggregate initialization. [*Example:*

```
struct A {
  int i;
  static int s;
  int j;
  int :17;
  int k;
} a = { 1, 2, 3 };
```

Here, the second initializer 2 initializes `a.j` and not the static data member `A::s`, and the third initializer 3 initializes `a.k` and not the anonymous bit-field before it. — *end example*]

1

An *initializer-list* is ill-formed if the number of *initializer-clause*s exceeds the number of members or elements to initialize. [*Example:*

```
char cv[4] = { 'a', 's', 'd', 'f', 0 };      // error
```

is ill-formed. — *end example*]

1

If there are fewer *initializer-clause*s in the list than there are members in the aggregate, then each member not explicitly initialized shall be initialized from its *brace-or-equal-initializer* or, if there is no *brace-or-equal-initializer*, from an empty initializer list (8.2435.1). [*Example:*

106) The syntax provides for empty *initializer-list*s, but nonetheless C++ does not have zero length arrays.

```
struct S { int a; const char* b; int c; int d = b[a]; };
S ss = { 1, "asdf" };
```

initializes `ss.a` with 1, `ss.b` with `"asdf"`, `ss.c` with the value of an expression of the form `int{}` (that is, `0`), and `ss.d` with the value of `ss.b[ss.a]` (that is, `'s'`), and in

```
struct X { int i, j, k = 42; };
X a[] = { 1, 2, 3, 4, 5, 6 };
X b[2] = { { 1, 2, 3 }, { 4, 5, 6 } };
```

`a` and `b` have the same value — *end example*]

1

If an aggregate class `C` contains a subaggregate member `m` that has no members for purposes of aggregate initialization, the *initializer-clause* for `m` shall not be omitted from an *initializer-list* for an object of type `C` unless the *initializer-clause*s for all members of `C` following `m` are also omitted. [*Example:*

```
struct S { } s;
struct A {
  S s1;
  int i1;
  S s2;
  int i2;
  S s3;
  int i3;
} a = {
  { },        // Required initialization
  0,
  s,          // Required initialization
  0
};            // Initialization not required for A::s3 because A::i3 is also not initialized
```

— *end example*]

1

If an incomplete or empty *initializer-list* leaves a member of reference type uninitialized, the program is ill-formed.

1

When initializing a multi-dimensional array, the *initializer-clause*s initialize the elements with the last (rightmost) index of the array varying the fastest (8.251.1). [*Example:*

```
int x[2][2] = { 3, 1, 4, 2 };
```

initializes `x[0][0]` to `3`, `x[0][1]` to `1`, `x[1][0]` to `4`, and `x[1][1]` to `2`. On the other hand,

```
float y[4][3] = {
  { 1 }, { 2 }, { 3 }, { 4 }
};
```

initializes the first column of `y` (regarded as a two-dimensional array) and leaves the rest zero. — *end example*]

1

Braces can be elided in an *initializer-list* as follows. If the *initializer-list* begins with a left brace, then the succeeding comma-separated list of *initializer-clause*s initializes the members of a subaggregate; it is

erroneous for there to be more *initializer-clause*s than members. If, however, the *initializer-list* for a subaggregate does not begin with a left brace, then only enough *initializer-clause*s from the list are taken to initialize the members of the subaggregate; any remaining *initializer-clause*s are left to initialize the next member of the aggregate of which the current subaggregate is a member. [*Example:*

```
float y[4][3] = {
  { 1, 3, 5 },
  { 2, 4, 6 },
  { 3, 5, 7 },
};
```

is a completely-braced initialization: 1, 3, and 5 initialize the first row of the array `y[0]`, namely `y[0][0]`, `y[0][1]`, and `y[0][2]`. Likewise the next two lines initialize `y[1]` and `y[2]`. The initializer ends early and therefore `y[3]`s elements are initialized as if explicitly initialized with an expression of the form `float()`, that is, are initialized with `0.0`. In the following example, braces in the *initializer-list* are elided; however the *initializer-list* has the same effect as the completely-braced *initializer-list* of the above example,

```
float y[4][3] = {
  1, 3, 5, 2, 4, 6, 3, 5, 7
};
```

The initializer for `y` begins with a left brace, but the one for `y[0]` does not, therefore three elements from the list are used. Likewise the next three are taken successively for `y[1]` and `y[2]`. — *end example*]

1

All implicit type conversions (Clause 4) are considered when initializing the aggregate member with an *assignment-expression*. If the *assignment-expression* can initialize a member, the member is initialized. Otherwise, if the member is itself a subaggregate, brace elision is assumed and the *assignment-expression* is considered for the initialization of the first member of the subaggregate. [*Note:* As specified above, brace elision cannot apply to subaggregates with no members for purposes of aggregate initialization; an *initializer-clause* for the entire subobject is required. — *end note*]

[*Example:*

```
struct A {
  int i;
  operator int();
};
struct B {
  A a1, a2;
  int z;
};
A a;
B b = { 4, a, a };
```

Braces are elided around the *initializer-clause* for `b.a1.i`. `b.a1.i` is initialized with 4, `b.a2` is initialized with `a`, `b.z` is initialized with whatever `a.operator int()` returns. — *end example*]

1

[*Note:* An aggregate array or an aggregate class may contain members of a class type with a user-provided constructor (12.30). Initialization of these aggregate objects is described in 12.1021.1. — *end note*]

1 [*Note:* Whether the initialization of aggregates with static storage duration is static or dynamic is specified in 3.1937.1 and 6.419. — *end note*]

2

When a union is initialized with a brace-enclosed initializer, the braces shall only contain an *initializer-clause* for the first non-static data member of the union. [*Example:*

```
union u { int a; const char* b; };
u a = { 1 };
u b = a;
u c = 1;                        // error
u d = { 0, "asdf" };            // error
u e = { "asdf" };               // error
```

— *end example*]

1 [*Note:* As described above, the braces around the *initializer-clause* for a union member can be omitted if the union is a member of another aggregate. — *end note*]

8.2115.1 Character arrays [dcl.init.string]

1

An array of narrow character type (3.3151.1), `char16_t` array, `char32_t` array, or `wchar_t` array can be initialized by a narrow string literal, `char16_t` string literal, `char32_t` string literal, or wide string literal, respectively, or by an appropriately-typed string literal enclosed in braces (2.453.1). Successive characters of the value of the string literal initialize the elements of the array. [*Example:*

```
char msg[] = "Syntax error on line %s\n";
```

shows a character array whose members are initialized with a *string-literal*. Note that because `'\n'` is a single character and because a trailing `'\0'` is appended, `sizeof(msg)` is `25`. — *end example*]

1

There shall not be more initializers than there are array elements. [*Example:*

```
char cv[4] = "asdf";            // error
```

is ill-formed since there is no space for the implied trailing `'\0'`. — *end example*]

1

If there are fewer initializers than there are array elements, each element not explicitly initialized shall be zero-initialized (8.821).

8.2156.1 References [dcl.init.ref]

1

A variable declared to be a `T&` or `T&&`, that is, "reference to type `T`" (8.97.1), shall be initialized by an object, or function, of type `T` or by an object that can be converted into a `T`. [*Example:*

```
int g(int);
void f() {
  int i;
  int& r = i;                   // r refers to i
  r = 1;                        // the value of i becomes 1
  int* p = &r;                  // p points to i
  int& rr = r;                  // rr refers to what r refers to, that is, to i
  int (&rg)(int) = g;           // rg refers to the function g
  rg(i);                        // calls function g
  int a[3];
  int (&ra)[3] = a;             // ra refers to the array a
  ra[1] = i;                    // modifies a[1]
}
```

— *end example*]

1

A reference cannot be changed to refer to another object after initialization. Note that initialization of a reference is treated very differently from assignment to it. Argument passing (5.955.1) and function value return (6.270.2) are initializations.

1

The initializer can be omitted for a reference only in a parameter declaration (8.360.1), in the declaration of a function return type, in the declaration of a class member within its class definition (9.194), and where the `extern` specifier is explicitly used. [*Example:*

```
int& r1;                    // error: initializer missing
extern int& r2;             // OK
```

— *end example*]

1

Given types "*cv1* `T1`" and "*cv2* `T2`," "*cv1* `T1`" is *reference-related* to "*cv2* `T2`" if `T1` is the same type as `T2`, or `T1` is a base class of `T2`. "*cv1* `T1`" is *reference-compatible* with "*cv2* `T2`" if `T1` is reference-related to `T2` and *cv1* is the same cv-qualification as, or greater cv-qualification than, *cv2*. In all cases where the reference-related or reference-compatible relationship of two types is used to establish the validity of a reference binding, and `T1` is a base class of `T2`, a program that necessitates such a binding is ill-formed if `T1` is an inaccessible (Clause 11) or ambiguous (10.52) base class of `T2`.

1

A reference to type "*cv1* `T1`" is initialized by an expression of type "*cv2* `T2`" as follows:

— If the reference is an lvalue reference and the initializer expression
  — is an lvalue (but is not a bit-field), and "*cv1* `T1`" is reference-compatible with "*cv2* `T2`," or
  — has a class type (i.e., `T2` is a class type), where `T1` is not reference-related to `T2`, and can be converted to an lvalue of type "*cv3* `T3`," where "*cv1* `T1`" is reference-compatible with "*cv3* `T3`"[107] (this conversion is selected by enumerating the applicable conversion functions (13.413.0.1) and choosing the best one through overload resolution (13.88)),

then the reference is bound to the initializer expression lvalue in the first case and to the lvalue result of the conversion in the second case (or, in either case, to the appropriate base class subobject of the object). [*Note:* The usual lvalue-to-rvalue (4.127), array-to-pointer (4.180), and function-to-pointer (4.220) standard conversions are not needed, and therefore are suppressed, when such direct bindings to lvalues are done. — *end note*]

[*Example:*

```
double d = 2.0;
double& rd = d;                 // rd refers to d
const double& rcd = d;          // rcd refers to d

struct A { };
struct B : A { operator int&(); } b;
A& ra = b;                      // ra refers to A subobject in b
const A& rca = b;               // rca refers to A subobject in b
int& ir = B();                  // ir refers to the result of B::operator int&
```

— *end example*]

107) This requires a conversion function (12.742.1) returning a reference type.

— Otherwise, the reference shall be an lvalue reference to a non-volatile const type (i.e., *cv1* shall be `const`), or the reference shall be an rvalue reference. [*Example:*

```
double& rd2 = 2.0;          // error: not an lvalue and reference not const
int  i = 2;
double& rd3 = i;            // error: type mismatch and reference not const
```

— *end example*]

— If the initializer expression

— is an xvalue (but not a bit-field), class prvalue, array prvalue or function lvalue and "*cv1* `T1`" is reference-compatible with "*cv2* `T2`", or

— has a class type (i.e., `T2` is a class type), where `T1` is not reference-related to `T2`, and can be converted to an xvalue, class prvalue, or function lvalue of type "*cv3* `T3`", where "*cv1* `T1`" is reference-compatible with "*cv3* `T3`" (see 13.413.0.1),

then the reference is bound to the value of the initializer expression in the first case and to the result of the conversion in the second case (or, in either case, to an appropriate base class subobject). In the second case, if the reference is an rvalue reference and the second standard conversion sequence of the user-defined conversion sequence includes an lvalue-to-rvalue conversion, the program is ill-formed.

[*Example:*

```
struct A { };
struct B : A { } b;
extern B f();
const A& rca2 = f();                // bound to the A subobject of the B rvalue.
A&& rra = f();                      // same as above
struct X {
  operator B();
  operator int&();
} x;
const A& r = x;                     // bound to the A subobject of the result of the conversion
int i2 = 42;
int&& rri = static_cast<int&&>(i2); // bound directly to i2
B&& rrb = x;                        // bound directly to the result of operator B
int&& rri2 = X();                   // error: lvalue-to-rvalue conversion applied to the
                                    // result of operator int&
```

— *end example*]

— Otherwise:

— If `T1` is a class type, user-defined conversions are considered using the rules for copy-initialization of an object of type "*cv1* `T1`" by user-defined conversion (8.821, 13.368.0.1); the program is ill-formed if the corresponding non-reference copy-initialization would be ill-formed. The result of the call to the conversion function, as described for the non-reference copy-initialization, is then used to direct-initialize the reference. The program is ill-formed if the direct-initialization does not result in a direct binding or if it involves a user-defined conversion.

— If `T1` is a non-class type, a temporary of type "*cv1* `T1`" is created and copy-initialized (8.821) from the initializer expression. The reference is then bound to the temporary.

If `T1` is reference-related to `T2`:

— *cv1* shall be the same cv-qualification as, or greater cv-qualification than, *cv2*; and

— if the reference is an rvalue reference, the initializer expression shall not be an lvalue.

[*Example:*

```
struct Banana { };
struct Enigma { operator const Banana(); };
void enigmatic() {
  typedef const Banana ConstBanana;
  Banana &&banana1 = ConstBanana(); // ill-formed
  Banana &&banana2 = Enigma();      // ill-formed
}

const double& rcd2 = 2;          // rcd2 refers to temporary with value 2.0
double&& rrd = 2;                // rrd refers to temporary with value 2.0
const volatile int cvi = 1;
const int& r2 = cvi;             // error: type qualifiers dropped
double d2 = 1.0;
double&& rrd2 = d2;              // error: copying lvalue of related type
int i3 = 2;
double&& rrd3 = i3;              // rrd3 refers to temporary with value 2.0
```

— *end example*]

In all cases except the last (i.e., creating and initializing a temporary from the initializer expression), the reference is said to *bind directly* to the initializer expression.

1 [*Note:* 12.306 describes the lifetime of temporaries bound to references. — *end note*]

8.2435.1 List-initialization [dcl.init.list]

1

List-initialization is initialization of an object or reference from a *braced-init-list*. Such an initializer is called an *initializer list*, and the comma-separated *initializer-clause*s of the list are called the *elements* of the initializer list. An initializer list may be empty. List-initialization can occur in direct-initialization or copy-initialization contexts; list-initialization in a direct-initialization context is called *direct-list-initialization* and list-initialization in a copy-initialization context is called *copy-list-initialization*. [*Note:* List-initialization can be used

— as the initializer in a variable definition (8.821)

— as the initializer in a new expression (5.2221.1)

— in a return statement (6.270.2)

— as a *for-range-initializer* (6.137)

— as a function argument (5.955.1)

— as a subscript (5.896.1)

— as an argument to a constructor invocation (8.821, 5.1108.1)

— as an initializer for a non-static data member (9.194)

— in a *mem-initializer* (12.1026.1)

— on the right-hand side of an assignment (5.3483)

[*Example:*

```
int a = {1};
std::complex<double> z{1,2};
new std::vector<std::string>{"once", "upon", "a", "time"};  // 4 string elements
f( {"Nicholas","Annemarie"} );  // pass list of two elements
return { "Norah" };             // return list of one element
int* e {};                      // initialization to zero / null pointer
x = double{1};                  // explicitly construct a double
std::map<std::string,int> anim = { {"bear",4}, {"cassowary",2}, {"tiger",7} };
```

— *end example*] — *end note*]

1

A constructor is an *initializer-list constructor* if its first parameter is of type `std::initializer_list<E>` or reference to possibly cv-qualified `std::initializer_list<E>` for some type `E`, and either there are no other parameters or else all other parameters have default arguments (8.545.1). [*Note:* Initializer-list constructors are favored over other constructors in list-initialization (13.425.0.1). Passing an initializer list as the argument to the constructor template `template<class T> C(T)` of a class `C` does not create an initializer-list constructor, because an initializer list argument causes the corresponding parameter to be a non-deduced context (14.2261.0.1). — *end note*] The template `std::initializer_list` is not predefined; if the header `<initializer_list>` is not included prior to a use of `std::initializer_list` — even an implicit use in which the type is not named (7.832.0.1) — the program is ill-formed.

1

List-initialization of an object or reference of type `T` is defined as follows:

— If `T` is an aggregate, aggregate initialization is performed (8.1817.1).

[*Example:*

```
double ad[] = { 1, 2.0 };          // OK
int ai[] = { 1, 2.0 };             // error: narrowing

struct S2 {
  int m1;
  double m2, m3;
};
S2 s21 = { 1, 2, 3.0 };            // OK
S2 s22 { 1.0, 2, 3 };              // error: narrowing
S2 s23 { };                        // OK: default to 0,0,0
```

— *end example*]

— Otherwise, if the initializer list has no elements and `T` is a class type with a default constructor, the object is value-initialized.

— Otherwise, if `T` is a specialization of `std::initializer_list<E>`, a prvalue `initializer_list` object is constructed as described below and used to initialize the object according to the rules for initialization of an object from a class of the same type (8.821).

— Otherwise, if `T` is a class type, constructors are considered. The applicable constructors are enumerated and the best one is chosen through overload resolution (13.88, 13.425.0.1). If a narrowing conversion (see below) is required to convert any of the arguments, the program is ill-formed.

[*Example:*

```
struct S {
  S(std::initializer_list<double>); // #1
  S(std::initializer_list<int>);    // #2
  S();                              // #3
  // ...
};
S s1 = { 1.0, 2.0, 3.0 };           // invoke #1
S s2 = { 1, 2, 3 };                 // invoke #2
S s3 = { };                         // invoke #3
```

— *end example*]

[*Example:*

```
struct Map {
  Map(std::initializer_list<std::pair<std::string,int>>);
};
Map ship = {{"Sophie",14}, {"Surprise",28}};
```

— *end example*]

[*Example:*

```
struct S {
  // no initializer-list constructors
  S(int, double, double);           // #1
  S();                              // #2
  // ...
};
S s1 = { 1, 2, 3.0 };               // OK: invoke #1
S s2 { 1.0, 2, 3 };                 // error: narrowing
S s3 { };                           // OK: invoke #2
```

— *end example*]

— Otherwise, if the initializer list has a single element of type `E` and either `T` is not a reference type or its referenced type is reference-related to `E`, the object or reference is initialized from that element; if a narrowing conversion (see below) is required to convert the element to `T`, the program is ill-formed.

[*Example:*

```
int x1 {2};                         // OK
int x2 {2.0};                       // error: narrowing
```

— *end example*]

— Otherwise, if `T` is a reference type, a prvalue temporary of the type referenced by `T` is copy-list-initialized or direct-list-initialized, depending on the kind of initialization for the reference, and the reference is bound to that temporary. [*Note:* As usual, the binding will fail and the program is ill-formed if the reference type is an lvalue reference to a non-const type. — *end note*]

[*Example:*

```
struct S {
  S(std::initializer_list<double>); // #1
  S(const std::string&);            // #2
  // ...
};
const S& r1 = { 1, 2, 3.0 };        // OK: invoke #1
```

```
const S& r2 { "Spinach" };          // OK: invoke #2
S& r3 = { 1, 2, 3 };                // error: initializer is not an lvalue
const int& i1 = { 1 };              // OK
const int& i2 = { 1.1 };            // error: narrowing
const int (&iar)[2] = { 1, 2 };     // OK: iar is bound to temporary array
```

— *end example*]

— Otherwise, if the initializer list has no elements, the object is value-initialized.

[*Example:*

```
int** pp {};                        // initialized to null pointer
```

— *end example*]

— Otherwise, the program is ill-formed.

[*Example:*

```
struct A { int i; int j; };
A a1 { 1, 2 };                      // aggregate initialization
A a2 { 1.2 };                       // error: narrowing
struct B {
  B(std::initializer_list<int>);
};
B b1 { 1, 2 };                      // creates initializer_list<int> and calls constructor
B b2 { 1, 2.0 };                    // error: narrowing
struct C {
  C(int i, double j);
};
C c1 = { 1, 2.2 };                  // calls constructor with arguments (1, 2.2)
C c2 = { 1.1, 2 };                  // error: narrowing

int j { 1 };                        // initialize to 1
int k { };                          // initialize to 0
```

— *end example*]

1

Within the *initializer-list* of a *braced-init-list*, the *initializer-clauses*, including any that result from pack expansions (14.703.1), are evaluated in the order in which they appear. That is, every value computation and side effect associated with a given *initializer-clause* is sequenced before every value computation and side effect associated with any *initializer-clause* that follows it in the comma-separated list of the *initializer-list*. [*Note:* This evaluation ordering holds regardless of the semantics of the initialization; for example, it applies when the elements of the *initializer-list* are interpreted as arguments of a constructor call, even though ordinarily there are no sequencing constraints on the arguments of a call. — *end note*]

1

An object of type `std::initializer_list<E>` is constructed from an initializer list as if the implementation allocated a temporary array of N elements of type `const E`, where N is the number of elements in the initializer list. Each element of that array is copy-initialized with the corresponding element of the initializer list, and the `std::initializer_list<E>` object is constructed to refer to that array. [*Note:* A constructor or conversion function selected for the copy shall be accessible (Clause 11) in the context of the initializer list. — *end note*] If a narrowing conversion is required to initialize any of the elements, the program is ill-formed.[*Example:*

```
struct X {
  X(std::initializer_list<double> v);
};
X x{ 1,2,3 };
```

The initialization will be implemented in a way roughly equivalent to this:

```
const double __a[3] = {double{1}, double{2}, double{3}};
X x(std::initializer_list<double>(__a, __a+3));
```

assuming that the implementation can construct an `initializer_list` object with a pair of pointers. — *end example*]

1

The array has the same lifetime as any other temporary object (12.306), except that initializing an `initializer_list` object from the array extends the lifetime of the array exactly like binding a reference to a temporary. [*Example:*

```
typedef std::complex<double> cmplx;
std::vector<cmplx> v1 = { 1, 2, 3 };

void f() {
  std::vector<cmplx> v2{ 1, 2, 3 };
  std::initializer_list<int> i3 = { 1, 2, 3 };
}

struct A {
  std::initializer_list<int> i4;
  A() : i4{ 1, 2, 3 } {}  // creates an A with a dangling reference
};
```

For `v1` and `v2`, the `initializer_list` object is a parameter in a function call, so the array created for `{ 1, 2, 3 }` has full-expression lifetime. For `i3`, the `initializer_list` object is a variable, so the array persists for the lifetime of the variable. For `i4`, the `initializer_list` object is initialized in a constructor's *ctor-initializer*, so the array persists only until the constructor exits, and so any use of the elements of `i4` after the constructor exits produces undefined behavior. — *end example*] [*Note:* The implementation is free to allocate the array in read-only memory if an explicit array with the same initializer could be so allocated. — *end note*]

1

A *narrowing conversion* is an implicit conversion

— from a floating-point type to an integer type, or

— from `long double` to `double` or `float`, or from `double` to `float`, except where the source is a constant expression and the actual value after conversion is within the range of values that can be represented (even if it cannot be represented exactly), or

— from an integer type or unscoped enumeration type to a floating-point type, except where the source is a constant expression and the actual value after conversion will fit into the target type and will produce the original value when converted back to the original type, or

— from an integer type or unscoped enumeration type to an integer type that cannot represent all the values of the original type, except where the source is a constant expression whose value after integral promotions will fit into the target type.

[*Note:* As indicated above, such conversions are not allowed at the top level in list-initializations. — *end note*] [*Example:*

```
int x = 999;                // x is not a constant expression
const int y = 999;
const int z = 99;
char c1 = x;                // OK, though it might narrow (in this case, it does narrow)
char c2{x};                 // error: might narrow
char c3{y};                 // error: narrows (assuming char is 8 bits)
char c4{z};                 // OK: no narrowing needed
unsigned char uc1 = {5};    // OK: no narrowing needed
unsigned char uc2 = {-1}; // error: narrows
unsigned int ui1 = {-1};    // error: narrows
signed int si1 =
  { (unsigned int)-1 };     // error: narrows
int ii = {2.0};             // error: narrows
float f1 { x };             // error: might narrow
float f2 { 7 };             // OK: 7 can be exactly represented as a float
int f(int);
int a[] =
  { 2, f(2), f(2.0) };      // OK: the double-to-int conversion is not at the top level
```

— *end example*]

9 Classes [class]

1

A class is a type. Its name becomes a *class-name* (9.172) within its scope.

class-name:
identifier
simple-template-id

*Class-specifier*s and *elaborated-type-specifier*s (7.808.0.1) are used to make *class-name*s. An object of a class consists of a (possibly empty) sequence of members and base class objects.

class-specifier:
class-head `{` *member-specification*$_{opt}$`}`

class-head:
class-key attribute-specifier-seq$_{opt}$ *class-head-name class-virt-specifier*$_{opt}$ *base-clause*$_{opt}$
class-key attribute-specifier-seq$_{opt}$ *base-clause*$_{opt}$

class-head-name:
nested-name-specifier$_{opt}$ *class-name*

class-virt-specifier:
`final`

class-key:
`class`
`struct`
`union`

A *class-specifier* whose *class-head* omits the *class-head-name* defines an unnamed class. [*Note:* An unnamed class thus can't be `final`. — *end note*]

1

A *class-name* is inserted into the scope in which it is declared immediately after the *class-name* is seen. The *class-name* is also inserted into the scope of the class itself; this is known as the *injected-class-name*. For purposes of access checking, the injected-class-name is treated as if it were a public member name. A *class-specifier* is commonly referred to as a class definition. A class is considered defined after the closing brace of its *class-specifier* has been seen even though its member functions are in general not yet defined. The optional *attribute-specifier-seq* appertains to the class; the attributes in the *attribute-specifier-seq* are thereafter considered attributes of the class whenever it is named.

1

If a class is marked with the *class-virt-specifier* `final` and it appears as a *base-type-specifier* in a *base-clause* (Clause 10), the program is ill-formed. Whenever a *class-key* is followed by a *class-head-name*, the *identifier* `final`, and a colon or left brace, `final` is interpreted as a *class-virt-specifier*. [*Example:*

```
struct A;
struct A final {};        // OK: definition of struct A,
                          // not value-initialization of variable final

struct X {
 struct C { constexpr operator int() { return 5; } };
 struct B final : C{};    // OK: definition of nested class B,
                          // not declaration of a bit-field member final
};
```

— *end example*]

1

Complete objects and member subobjects of class type shall have nonzero size.[108] [*Note:* Class objects can be assigned, passed as arguments to functions, and returned by functions (except objects of classes for which copying or moving has been restricted; see 12.1577). Other plausible operators, such as equality comparison, can be defined by the user; see 13.1122. — *end note*]

1

A *union* is a class defined with the *class-key* `union`; it holds at most one data member at a time (9.815). [*Note:* Aggregates of class type are described in 8.1817.1. — *end note*]

1

A *trivially copyable class* is a class that:

— has no non-trivial copy constructors (12.1577),

— has no non-trivial move constructors (12.1577),

— has no non-trivial copy assignment operators (13.1178.1, 12.1577),

— has no non-trivial move assignment operators (13.1178.1, 12.1577), and

— has a trivial destructor (12.807).

A *trivial class* is a class that has a default constructor (12.30), has no non-trivial default constructors, and is trivially copyable. [*Note:* In particular, a trivially copyable or trivial class does not have virtual functions or virtual base classes. — *end note*]

1

A *standard-layout class* is a class that:

— has no non-static data members of type non-standard-layout class (or array of such types) or reference,

— has no virtual functions (10.113) and no virtual base classes (10.31),

— has the same access control (Clause 11) for all non-static data members,

— has no non-standard-layout base classes,

— either has no non-static data members in the most derived class and at most one base class with non-static data members, or has no base classes with non-static data members, and

— has no base classes of the same type as the first non-static data member.[109]

1

A *standard-layout struct* is a standard-layout class defined with the *class-key* `struct` or the *class-key* `class`. A *standard-layout union* is a standard-layout class defined with the *class-key* `union`.

1

[*Note:* Standard-layout classes are useful for communicating with code written in other programming languages. Their layout is specified in 9.194. — *end note*]

1

108) Base class subobjects are not so constrained.

109) This ensures that two subobjects that have the same class type and that belong to the same most derived object are not allocated at the same address (5.3247).

A *POD struct*[110] is a non-union class that is both a trivial class and a standard-layout class, and has no non-static data members of type non-POD struct, non-POD union (or array of such types). Similarly, a *POD union* is a union that is both a trivial class and a standard-layout class, and has no non-static data members of type non-POD struct, non-POD union (or array of such types). A *POD class* is a class that is either a POD struct or a POD union.

[*Example:*

```
struct N {          // neither trivial nor standard-layout
  int i;
  int j;
  virtual ~N();
};

struct T {          // trivial but not standard-layout
  int i;
private:
  int j;
};

struct SL {         // standard-layout but not trivial
  int i;
  int j;
  ~SL();
};

struct POD {        // both trivial and standard-layout
  int i;
  int j;
};
```

— *end example*]

1

If a *class-head-name* contains a *nested-name-specifier*, the *class-specifier* shall refer to a class that was previously declared directly in the class or namespace to which the *nested-name-specifier* refers, or in an element of the inline namespace set (7.1149.1) of that namespace (i.e., not merely inherited or introduced by a *using-declaration*), and the *class-specifier* shall appear in a namespace enclosing the previous declaration. In such cases, the *nested-name-specifier* of the *class-head-name* of the definition shall not begin with a *decltype-specifier*.

9.172 Class names [class.name]

1 A class definition introduces a new type. [*Example:*

```
struct X { int a; };
struct Y { int a; };
X a1;
Y a2;
int a3;
```

declares three variables of three different types. This implies that

```
a1 = a2;                    // error: Y assigned to X
a1 = a3;                    // error: int assigned to X
```

110) The acronym POD stands for "plain old data".

are type mismatches, and that

```
int f(X);
int f(Y);
```

declare an overloaded (Clause 13) function `f()` and not simply a single function `f()` twice. For the same reason,

```
struct S { int a; };
struct S { int a; };            // error, double definition
```

is ill-formed because it defines `S` twice. — *end example*]

2

A class declaration introduces the class name into the scope where it is declared and hides any class, variable, function, or other declaration of that name in an enclosing scope (3.464). If a class name is declared in a scope where a variable, function, or enumerator of the same name is also declared, then when both declarations are in scope, the class can be referred to only using an *elaborated-type-specifier* (3.1395.1). [*Example:*

```
struct stat {
  // ...
};

stat gstat;                     // use plain stat to
                                // define variable

int stat(struct stat*);         // redeclare stat as function

void f() {
  struct stat* ps;              // struct prefix needed
                                // to name struct stat
  stat(ps);                     // call stat()
}
```

— *end example*] A *declaration* consisting solely of *class-key identifier;* is either a redeclaration of the name in the current scope or a forward declaration of the identifier as a class name. It introduces the class name into the current scope. [*Example:*

```
struct s { int a; };

void g() {
  struct s;                     // hide global struct s
                                // with a block-scope declaration
  s* p;                         // refer to local struct s
  struct s { char* p; };        // define local struct s
  struct s;                     // redeclaration, has no effect
}
```

— *end example*] [*Note:* Such declarations allow definition of classes that refer to each other. [*Example:*

```
class Vector;

class Matrix {
  // ...
  friend Vector operator*(const Matrix&, const Vector&);
};
```

```
class Vector {
  // ...
  friend Vector operator*(const Matrix&, const Vector&);
};
```

Declaration of `friend`s is described in 11.94, operator functions in 13.1122. — *end example*] — *end note*]

1

[*Note:* An *elaborated-type-specifier* (7.808.0.1) can also be used as a *type-specifier* as part of a declaration. It differs from a class declaration in that if a class of the elaborated name is in scope the elaborated name will refer to it. — *end note*] [*Example:*

```
struct s { int a; };

void g(int s) {
  struct s* p = new struct s;    // global s
  p->a = s;                      // parameter s
}
```

— *end example*]

1 [*Note:* The declaration of a class name takes effect immediately after the *identifier* is seen in the class definition or *elaborated-type-specifier*. For example,

```
class A * A;
```

first specifies `A` to be the name of a class and then redefines it as the name of a pointer to an object of that class. This means that the elaborated form `class A` must be used to refer to the class. Such artistry with names can be confusing and is best avoided. — *end note*]

2

A *typedef-name* (7.235.1) that names a class type, or a cv-qualified version thereof, is also a *class-name*. If a *typedef-name* that names a cv-qualified class type is used where a *class-name* is required, the cv-qualifiers are ignored. A *typedef-name* shall not be used as the *identifier* in a *class-head*.

9.194 Class members [class.mem]

member-specification:
- *member-declaration member-specification*$_{opt}$
- *access-specifier* : *member-specification*$_{opt}$

member-declaration:
- *attribute-specifier-seq*$_{opt}$ *decl-specifier-seq*$_{opt}$ *member-declarator-list*$_{opt}$;
- *function-definition*
- *using-declaration*
- *static_assert-declaration*
- *template-declaration*
- *alias-declaration*
- *empty-declaration*

member-declarator-list:
- *member-declarator*
- *member-declarator-list* , *member-declarator*

member-declarator:
- *declarator virt-specifier-seq*$_{opt}$ *pure-specifier*$_{opt}$
- *declarator brace-or-equal-initializer*$_{opt}$
- *identifier*$_{opt}$ *attribute-specifier-seq*$_{opt}$: *constant-expression*

virt-specifier-seq:
    virt-specifier
    virt-specifier-seq virt-specifier
virt-specifier:
    `override`
    `final`
pure-specifier:
    `= 0`

1

The *member-specification* in a class definition declares the full set of members of the class; no member can be added elsewhere. Members of a class are data members, member functions (9.401), nested types, and enumerators. Data members and member functions are static or non-static; see 9.559. Nested types are classes (9.172, 9.960) and enumerations (7.1001) defined in the class, and arbitrary types declared as members by use of a typedef declaration (7.235.1). The enumerators of an unscoped enumeration (7.1001) defined in the class are members of the class. Except when used to declare friends (11.94), to declare an unnamed bit-field (9.921), or to introduce the name of a member of a base class into a derived class (7.1311.1), or when the declaration is an *empty-declaration*, *member-declaration*s declare members of the class, and each such *member-declaration* shall declare at least one member name of the class. A member shall not be declared twice in the *member-specification*, except that a nested class or member class template can be declared and then later defined, and except that an enumeration can be introduced with an *opaque-enum-declaration* and later redeclared with an *enum-specifier*.

1

A class is considered a completely-defined object type (3.2955) (or complete type) at the closing `}` of the *class-specifier*. Within the class *member-specification*, the class is regarded as complete within function bodies, default arguments, *using-declaration*s introducing inheriting constructors (12.2400), *exception-specification*s, and *brace-or-equal-initializer*s for non-static data members (including such things in nested classes). Otherwise it is regarded as incomplete within its own class *member-specification*.

1 [*Note:* A single name can denote several function members provided their types are sufficiently different (Clause 13). — *end note*]

2

A *brace-or-equal-initializer* shall appear only in the declaration of a data member. (For static data members, see 9.595.1; for non-static data members, see 12.1026.1).

1 A member shall not be declared with the `extern` or `register` *storage-class-specifier*. Within a class definition, a member shall not be declared with the `thread_local` *storage-class-specifier* unless also declared `static`.

2 The *decl-specifier-seq* may be omitted in constructor, destructor, and conversion function declarations only; when declaring another kind of member the *decl-specifier-seq* shall contain a *type-specifier* that is not a *cv-qualifier*. The *member-declarator-list* can be omitted only after a *class-specifier* or an *enum-specifier* or in a `friend` declaration (11.94). A *pure-specifier* shall be used only in the declaration of a virtual function (10.113).

3 The optional *attribute-specifier-seq* in a *member-declaration* appertains to each of the entities declared by the *member-declarator*s; it shall not appear if the optional *member-declarator-list* is omitted.

4

A *virt-specifier-seq* shall contain at most one of each *virt-specifier*. A *virt-specifier-seq* shall appear only in the declaration of a virtual member function (10.113).

1

Non-`static` (9.559) data members shall not have incomplete types. In particular, a class `C` shall not contain a non-static member of class `C`, but it can contain a pointer or reference to an object of class `C`.

1 [*Note:* See 5.398 for restrictions on the use of non-static data members and non-static member functions. — *end note*]

2

[*Note:* The type of a non-static member function is an ordinary function type, and the type of a non-static data member is an ordinary object type. There are no special member function types or data member types. — *end note*]

1

[*Example:* A simple example of a class definition is

```
struct tnode {
  char tword[20];
  int count;
  tnode* left;
  tnode* right;
};
```

which contains an array of twenty characters, an integer, and two pointers to objects of the same type. Once this definition has been given, the declaration

```
tnode s, *sp;
```

declares `s` to be a `tnode` and `sp` to be a pointer to a `tnode`. With these declarations, `sp->count` refers to the `count` member of the object to which `sp` points; `s.left` refers to the `left` subtree pointer of the object `s`; and `s.right->tword[0]` refers to the initial character of the `tword` member of the `right` subtree of `s`. — *end example*]

1

Nonstatic data members of a (non-union) class with the same access control (Clause 11) are allocated so that later members have higher addresses within a class object. The order of allocation of non-static data members with different access control is unspecified (Clause 11). Implementation alignment requirements might cause two adjacent members not to be allocated immediately after each other; so might requirements for space for managing virtual functions (10.113) and virtual base classes (10.31).

1

If `T` is the name of a class, then each of the following shall have a name different from `T`:

— every static data member of class `T`;

— every member function of class `T` [*Note:* This restriction does not apply to constructors, which do not have names (12.30) — *end note*];

— every member of class `T` that is itself a type;

— every enumerator of every member of class `T` that is an unscoped enumerated type; and

— every member of every anonymous union that is a member of class `T`.

1

In addition, if class `T` has a user-declared constructor (12.30), every non-static data member of class `T` shall have a name different from `T`.

1

Two standard-layout struct (Clause 9) types are *layout-compatible* if they have the same number of non-static data members and corresponding non-static data members (in declaration order) have layout-compatible types (3.2955).

1 Two standard-layout union (Clause 9) types are *layout-compatible* if they have the same number of non-static data members and corresponding non-static data members (in any order) have layout-compatible types (3.2955).

2

If a standard-layout union contains two or more standard-layout structs that share a common initial sequence, and if the standard-layout union object currently contains one of these standard-layout structs, it is permitted to inspect the common initial part of any of them. Two standard-layout structs share a common initial sequence if corresponding members have layout-compatible types and either neither member is a bit-field or both are bit-fields with the same width for a sequence of one or more initial members.

1

If a standard-layout class object has any non-static data members, its address is the same as the address of its first non-static data member. Otherwise, its address is the same as the address of its first base class subobject (if any). [*Note:* There might therefore be unnamed padding within a standard-layout struct object, but not at its beginning, as necessary to achieve appropriate alignment. — *end note*]

9.401 Member functions [class.mfct]

1

Functions declared in the definition of a class, excluding those declared with a `friend` specifier (11.94), are called member functions of that class. A member function may be declared `static` in which case it is a *static* member function of its class (9.559); otherwise it is a *non-static* member function of its class (9.465.1, 9.508.1).

1

A member function may be defined (8.706) in its class definition, in which case it is an *inline* member function (7.94.1), or it may be defined outside of its class definition if it has already been declared but not defined in its class definition. A member function definition that appears outside of the class definition shall appear in a namespace scope enclosing the class definition. Except for member function definitions that appear outside of a class definition, and except for explicit specializations of member functions of class templates and member function templates (14.1614) appearing outside of the class definition, a member function shall not be redeclared.

1

An `inline` member function (whether static or non-static) may also be defined outside of its class definition provided either its declaration in the class definition or its definition outside of the class definition declares the function as `inline`. [*Note:* Member functions of a class in namespace scope have external linkage. Member functions of a local class (9.975) have no linkage. See 3.1459. — *end note*]

1

There shall be at most one definition of a non-inline member function in a program; no diagnostic is required. There may be more than one `inline` member function definition in a program. See 3.91 and 7.94.1.

1

If the definition of a member function is lexically outside its class definition, the member function name shall be qualified by its class name using the `::` operator. [*Note:* A name used in a member function definition (that is, in the *parameter-declaration-clause* including the default arguments (8.545.1) or in the member function body) is looked up as described in 3.923. — *end note*] [*Example:*

```
struct X {
  typedef int T;
  static T count;
  void f(T);
};
```

```
void X::f(T t = count) { }
```

The member function `f` of class `X` is defined in global scope; the notation `X::f` specifies that the function `f` is a member of class `X` and in the scope of class `X`. In the function definition, the parameter type `T` refers to the typedef member `T` declared in class `X` and the default argument `count` refers to the static data member `count` declared in class `X`. — *end example*]

1

A `static` local variable in a member function always refers to the same object, whether or not the member function is `inline`.

1

Previously declared member functions may be mentioned in `friend` declarations.

1

Member functions of a local class shall be defined inline in their class definition, if they are defined at all.

1

[*Note:* A member function can be declared (but not defined) using a typedef for a function type. The resulting member function has exactly the same type as it would have if the function declarator were provided explicitly, see 8.360.1. For example,

```
typedef void fv(void);
typedef void fvc(void) const;
struct S {
  fv memfunc1;      // equivalent to: void memfunc1(void);
  void memfunc2();
  fvc memfunc3;     // equivalent to: void memfunc3(void) const;
};
fv  S::* pmfv1 = &S::memfunc1;
fv  S::* pmfv2 = &S::memfunc2;
fvc S::* pmfv3 = &S::memfunc3;
```

Also see 14.326. — *end note*]

9.465.1 Nonstatic member functions [class.mfct.non-static]

1

A *non-static* member function may be called for an object of its class type, or for an object of a class derived (Clause 10) from its class type, using the class member access syntax (5.1194.1, 13.230.0.1). A non-static member function may also be called directly using the function call syntax (5.955.1, 13.230.0.1) from within the body of a member function of its class or of a class derived from its class.

1

If a non-static member function of a class `X` is called for an object that is not of type `X`, or of a type derived from `X`, the behavior is undefined.

1

When an *id-expression* (5.398) that is not part of a class member access syntax (5.1194.1) and not used to form a pointer to member (5.1898.1) is used in a member of class `X` in a context where `this` can be used (5.398.1), if name lookup (3.923) resolves the name in the *id-expression* to a non-static non-type member of some class `C`, and if either the *id-expression* is potentially evaluated or `C` is `X` or a base class of `X`, the *id-expression* is transformed into a class member access expression (5.1194.1) using `(*this)` (9.508.1) as the *postfix-expression* to the left of the `.` operator. [*Note:* If `C` is not `X` or a base class of `X`, the class member access expression is ill-formed. — *end note*] Similarly during name lookup, when an *unqualified-id* (5.398)

used in the definition of a member function for class `X` resolves to a `static` member, an enumerator or a nested type of class `X` or of a base class of `X`, the *unqualified-id* is transformed into a *qualified-id* (5.398) in which the *nested-name-specifier* names the class of the member function. [*Example:*

```
struct tnode {
  char tword[20];
  int count;
  tnode* left;
  tnode* right;
  void set(const char*, tnode* l, tnode* r);
};

void tnode::set(const char* w, tnode* l, tnode* r) {
  count = strlen(w)+1;
  if (sizeof(tword)<=count)
      perror("tnode string too long");
  strcpy(tword,w);
  left = l;
  right = r;
}

void f(tnode n1, tnode n2) {
  n1.set("abc",&n2,0);
  n2.set("def",0,0);
}
```

In the body of the member function `tnode::set`, the member names `tword`, `count`, `left`, and `right` refer to members of the object for which the function is called. Thus, in the call `n1.set("abc",&n2,0)`, `tword` refers to `n1.tword`, and in the call `n2.set("def",0,0)`, it refers to `n2.tword`. The functions `strlen`, `perror`, and `strcpy` are not members of the class `tnode` and should be declared elsewhere.[111] — *end example*]

1

A non-static member function may be declared `const`, `volatile`, or `const volatile`. These *cv-qualifiers* affect the type of the `this` pointer (9.508.1). They also affect the function type (8.360.1) of the member function; a member function declared `const` is a *const* member function, a member function declared `volatile` is a *volatile* member function and a member function declared `const volatile` is a *const volatile* member function. [*Example:*

```
struct X {
  void g() const;
  void h() const volatile;
};
```

`X::g` is a `const` member function and `X::h` is a `const volatile` member function. — *end example*]

1

A non-static member function may be declared with a *ref-qualifier* (8.360.1); see 13.133.1.

1 A non-static member function may be declared *virtual* (10.113) or *pure virtual* (10.276).

9.508.1 The `this` pointer [class.this]

1

In the body of a non-static (9.401) member function, the keyword `this` is a prvalue expression whose value is the address of the object for which the function is called. The type of `this` in a member function of

111) See, for example, `<cstring>` (21.261).

a class `X` is `X*`. If the member function is declared `const`, the type of `this` is `const X*`, if the member function is declared `volatile`, the type of `this` is `volatile X*`, and if the member function is declared `const volatile`, the type of `this` is `const volatile X*`. [*Note:* thus in a `const` member function, the object for which the function is called is accessed through a `const` access path. — *end note*] [*Example:*

```
struct s {
  int a;
  int f() const;
  int g() { return a++; }
  int h() const { return a++; } // error
};

int s::f() const { return a; }
```

The `a++` in the body of `s::h` is ill-formed because it tries to modify (a part of) the object for which `s::h()` is called. This is not allowed in a `const` member function because `this` is a pointer to `const`; that is, `*this` has `const` type. — *end example*]

1

Similarly, `volatile` semantics (7.567.0.1) apply in `volatile` member functions when accessing the object and its non-static data members.

1

A *cv-qualified* member function can be called on an object-expression (5.1194.1) only if the object-expression is as cv-qualified or less-cv-qualified than the member function. [*Example:*

```
void k(s& x, const s& y) {
  x.f();
  x.g();
  y.f();
  y.g();                    // error
}
```

The call `y.g()` is ill-formed because `y` is `const` and `s::g()` is a non-`const` member function, that is, `s::g()` is less-qualified than the object-expression `y`. — *end example*]

1 Constructors (12.30) and destructors (12.807) shall not be declared `const`, `volatile` or `const volatile`. [*Note:* However, these functions can be invoked to create and destroy objects with cv-qualified types, see (12.30) and (12.807). — *end note*]

9.559 Static members [class.static]

1

A data or function member of a class may be declared `static` in a class definition, in which case it is a *static member* of the class.

1

A `static` member `s` of class `X` may be referred to using the *qualified-id* expression `X::s`; it is not necessary to use the class member access syntax (5.1194.1) to refer to a `static` member. A `static` member may be referred to using the class member access syntax, in which case the object expression is evaluated. [*Example:*

```
struct process {
  static void reschedule();
};
process& g();
```

```
void f() {
  process::reschedule();        // OK: no object necessary
  g().reschedule();             // g() is called
}
```

— *end example*]

1

A `static` member may be referred to directly in the scope of its class or in the scope of a class derived (Clause 10) from its class; in this case, the `static` member is referred to as if a *qualified-id* expression was used, with the *nested-name-specifier* of the *qualified-id* naming the class scope from which the static member is referenced. [*Example:*

```
int g();
struct X {
  static int g();
};
struct Y : X {
  static int i;
};
int Y::i = g();                 // equivalent to Y::g();
```

— *end example*]

1

If an *unqualified-id* (5.398) is used in the definition of a `static` member following the member's *declarator-id*, and name lookup (3.952.1) finds that the *unqualified-id* refers to a `static` member, enumerator, or nested type of the member's class (or of a base class of the member's class), the *unqualified-id* is transformed into a *qualified-id* expression in which the *nested-name-specifier* names the class scope from which the member is referenced. [*Note:* See 5.398 for restrictions on the use of non-static data members and non-static member functions. — *end note*]

1

Static members obey the usual class member access rules (Clause 11). When used in the declaration of a class member, the `static` specifier shall only be used in the member declarations that appear within the *member-specification* of the class definition. [*Note:* It cannot be specified in member declarations that appear in namespace scope. — *end note*]

9.583.1 Static member functions [class.static.mfct]

1 [*Note:* The rules described in 9.401 apply to `static` member functions. — *end note*]

2

[*Note:* A `static` member function does not have a `this` pointer (9.508.1). — *end note*] A `static` member function shall not be `virtual`. There shall not be a `static` and a non-static member function with the same name and the same parameter types (13.12). A `static` member function shall not be declared `const`, `volatile`, or `const volatile`.

9.595.1 Static data members [class.static.data]

1

A `static` data member is not part of the subobjects of a class. If a `static` data member is declared `thread_local` there is one copy of the member per thread. If a `static` data member is not declared `thread_local` there is one copy of the data member that is shared by all the objects of the class.

1

The declaration of a `static` data member in its class definition is not a definition and may be of an incomplete type other than cv-qualified `void`. The definition for a `static` data member shall appear in a namespace scope enclosing the member's class definition. In the definition at namespace scope, the name of the `static` data member shall be qualified by its class name using the `::` operator. The *initializer* expression in the definition of a `static` data member is in the scope of its class (3.760.1). [*Example:*

```
class process {
  static process* run_chain;
  static process* running;
};

process* process::running = get_main();
process* process::run_chain = running;
```

The `static` data member `run_chain` of class `process` is defined in global scope; the notation `process::run_chain` specifies that the member `run_chain` is a member of class `process` and in the scope of class `process`. In the `static` data member definition, the *initializer* expression refers to the `static` data member `running` of class `process`. — *end example*]

[*Note:* Once the `static` data member has been defined, it exists even if no objects of its class have been created. [*Example:* in the example above, `run_chain` and `running` exist even if no objects of class `process` are created by the program. — *end example*] — *end note*]

1

If a non-volatile `const static` data member is of integral or enumeration type, its declaration in the class definition can specify a *brace-or-equal-initializer* in which every *initializer-clause* that is an *assignment-expression* is a constant expression (5.3643). A `static` data member of literal type can be declared in the class definition with the `constexpr` specifier; if so, its declaration shall specify a *brace-or-equal-initializer* in which every *initializer-clause* that is an *assignment-expression* is a constant expression. [*Note:* In both these cases, the member may appear in constant expressions. — *end note*] The member shall still be defined in a namespace scope if it is odr-used (3.91) in the program and the namespace scope definition shall not contain an *initializer*.

1

[*Note:* There shall be exactly one definition of a `static` data member that is odr-used (3.91) in a program; no diagnostic is required. — *end note*] Unnamed classes and classes contained directly or indirectly within unnamed classes shall not contain `static` data members.

1

`Static` data members of a class in namespace scope have external linkage (3.1459). A local class shall not have `static` data members.

1

`Static` data members are initialized and destroyed exactly like non-local variables (3.1937.1, 3.2200.1).

1 A `static` data member shall not be `mutable` (7.49.1).

9.815 Unions [class.union]

1

In a union, at most one of the non-static data members can be active at any time, that is, the value of at most one of the non-static data members can be stored in a union at any time. [*Note:* One special guarantee is made in order to simplify the use of unions: If a standard-layout union contains several standard-layout structs that share a common initial sequence (9.194), and if an object of this standard-layout union type contains one of the standard-layout structs, it is permitted to inspect the common initial sequence of any

of standard-layout struct members; see 9.194. — *end note*] The size of a union is sufficient to contain the largest of its non-static data members. Each non-static data member is allocated as if it were the sole member of a struct. All non-static data members of a union object have the same address.

1

A union can have member functions (including constructors and destructors), but not virtual (10.113) functions. A union shall not have base classes. A union shall not be used as a base class. If a union contains a non-static data member of reference type the program is ill-formed. [*Note:* If any non-static data member of a union has a non-trivial default constructor (12.30), copy constructor (12.1577), move constructor (12.1577), copy assignment operator (12.1577), move assignment operator (12.1577), or destructor (12.807), the corresponding member function of the union must be user-provided or it will be implicitly deleted (8.793.1) for the union. — *end note*]

1

[*Example:* Consider the following union:

```
union U {
  int i;
  float f;
  std::string s;
};
```

Since `std::string` (21.26) declares non-trivial versions of all of the special member functions, `U` will have an implicitly deleted default constructor, copy/move constructor, copy/move assignment operator, and destructor. To use `U`, some or all of these member functions must be user-provided. — *end example*]

1

[*Note:* In general, one must use explicit destructor calls and placement new operators to change the active member of a union. — *end note*] [*Example:* Consider an object `u` of a `union` type `U` having non-static data members `m` of type `M` and `n` of type `N`. If `M` has a non-trivial destructor and `N` has a non-trivial constructor (for instance, if they declare or inherit virtual functions), the active member of `u` can be safely switched from `m` to `n` using the destructor and placement new operator as follows:

```
u.m.~M();
new (&u.n) N;
```

— *end example*]

1

A union of the form

`union {` *member-specification* `} ;`

is called an *anonymous union*; it defines an unnamed object of unnamed type. The *member-specification* of an anonymous union shall only define non-static data members. [*Note:* Nested types, anonymous unions, and functions cannot be declared within an anonymous union. — *end note*] The names of the members of an anonymous union shall be distinct from the names of any other entity in the scope in which the anonymous union is declared. For the purpose of name lookup, after the anonymous union definition, the members of the anonymous union are considered to have been defined in the scope in which the anonymous union is declared. [*Example:*

```
void f() {
  union { int a; const char* p; };
  a = 1;
  p = "Jennifer";
}
```

Here `a` and `p` are used like ordinary (nonmember) variables, but since they are union members they have the same address. — *end example*]

1

Anonymous unions declared in a named namespace or in the global namespace shall be declared `static`. Anonymous unions declared at block scope shall be declared with any storage class allowed for a block-scope variable, or with no storage class. A storage class is not allowed in a declaration of an anonymous union in a class scope. An anonymous union shall not have `private` or `protected` members (Clause 11). An anonymous union shall not have function members.

1 A union for which objects, pointers, or references are declared is not an anonymous union. [*Example:*

```
void f() {
  union { int aa; char* p; } obj, *ptr = &obj;
  aa = 1;                          // error
  ptr->aa = 1;                     // OK
}
```

The assignment to plain `aa` is ill-formed since the member name is not visible outside the union, and even if it were visible, it is not associated with any particular object. — *end example*] [*Note:* Initialization of unions with no user-declared constructors is described in (8.1817.1). — *end note*]

2

A *union-like class* is a union or a class that has an anonymous union as a direct member. A union-like class `X` has a set of *variant members*. If `X` is a union, a non-static data member of `X` that is not an anonymous union is a variant member of `X`. In addition, a non-static data member of an anonymous union that is a member of `X` is also a variant member of `X`. At most one variant member of a union may have a *brace-or-equal-initializer*. [*Example:*

```
union U {
  int x = 0;
  union { };
  union {
    int z;
    int y = 1; // error: initialization for second variant member of U
  };
};
```

— *end example*]

9.921 Bit-fields [class.bit]

1

A *member-declarator* of the form

$$\textit{identifier}_{opt}\ \textit{attribute-specifier-seq}_{opt}\texttt{:}\ \textit{constant-expression}$$

specifies a bit-field; its length is set off from the bit-field name by a colon. The optional *attribute-specifier-seq* appertains to the entity being declared. The bit-field attribute is not part of the type of the class member. The *constant-expression* shall be an integral constant expression with a value greater than or equal to zero. The value of the integral constant expression may be larger than the number of bits in the object representation (3.2955) of the bit-field's type; in such cases the extra bits are used as padding bits and do not participate in the value representation (3.2955) of the bit-field. Allocation of bit-fields within a class object is implementation-defined. Alignment of bit-fields is implementation-defined. Bit-fields are packed into some addressable allocation unit. [*Note:* Bit-fields straddle allocation units on some machines and not on others. Bit-fields are assigned right-to-left on some machines, left-to-right on others. — *end note*]

1

A declaration for a bit-field that omits the *identifier* declares an *unnamed* bit-field. Unnamed bit-fields are not members and cannot be initialized. [*Note:* An unnamed bit-field is useful for padding to conform to externally-imposed layouts. — *end note*] As a special case, an unnamed bit-field with a width of zero specifies alignment of the next bit-field at an allocation unit boundary. Only when declaring an unnamed bit-field may the value of the *constant-expression* be equal to zero.

1

A bit-field shall not be a static member. A bit-field shall have integral or enumeration type (3.3151.1). A `bool` value can successfully be stored in a bit-field of any nonzero size. The address-of operator `&` shall not be applied to a bit-field, so there are no pointers to bit-fields. A non-const reference shall not be bound to a bit-field (8.2156.1). [*Note:* If the initializer for a reference of type `const T&` is an lvalue that refers to a bit-field, the reference is bound to a temporary initialized to hold the value of the bit-field; the reference is not bound to the bit-field directly. See 8.2156.1. — *end note*]

1

If the value `true` or `false` is stored into a bit-field of type `bool` of any size (including a one bit bit-field), the original `bool` value and the value of the bit-field shall compare equal. If the value of an enumerator is stored into a bit-field of the same enumeration type and the number of bits in the bit-field is large enough to hold all the values of that enumeration type (7.1001), the original enumerator value and the value of the bit-field shall compare equal. [*Example:*

```
enum BOOL { FALSE=0, TRUE=1 };
struct A {
  BOOL b:1;
};
A a;
void f() {
  a.b = TRUE;
  if (a.b == TRUE)              // yields true
    { /* ... */ }
}
```

— *end example*]

9.960 Nested class declarations [class.nest]

1

A class can be declared within another class. A class declared within another is called a *nested* class. The name of a nested class is local to its enclosing class. The nested class is in the scope of its enclosing class. [*Note:* See 5.398 for restrictions on the use of non-static data members and non-static member functions. — *end note*]

[*Example:*

```
int x;
int y;

struct enclose {
  int x;
  static int s;

  struct inner {
    void f(int i) {
      int a = sizeof(x);        // OK: operand of sizeof is an unevaluated operand
```

```
      x = i;                    // error: assign to enclose::x
      s = i;                    // OK: assign to enclose::s
      ::x = i;                  // OK: assign to global x
      y = i;                    // OK: assign to global y
    }
    void g(enclose* p, int i) {
      p->x = i;                 // OK: assign to enclose::x
    }
  };
};

inner* p = 0;                   // error: inner not in scope
```

— *end example*]

1

Member functions and static data members of a nested class can be defined in a namespace scope enclosing the definition of their class. [*Example:*

```
struct enclose {
  struct inner {
    static int x;
    void f(int i);
  };
};

int enclose::inner::x = 1;

void enclose::inner::f(int i) { /* ... */ }
```

— *end example*]

1

If class `X` is defined in a namespace scope, a nested class `Y` may be declared in class `X` and later defined in the definition of class `X` or be later defined in a namespace scope enclosing the definition of class `X`. [*Example:*

```
class E {
  class I1;                     // forward declaration of nested class
  class I2;
  class I1 { };                 // definition of nested class
};
class E::I2 { };                // definition of nested class
```

— *end example*]

1

Like a member function, a friend function (11.94) defined within a nested class is in the lexical scope of that class; it obeys the same rules for name binding as a static member function of that class (9.559), but it has no special access rights to members of an enclosing class.

9.975 Local class declarations [class.local]

1

A class can be declared within a function definition; such a class is called a *local* class. The name of a local class is local to its enclosing scope. The local class is in the scope of the enclosing scope, and has the same

access to names outside the function as does the enclosing function. Declarations in a local class shall not odr-use (3.91) a variable with automatic storage duration from an enclosing scope. [*Example:*

```
int x;
void f() {
  static int s ;
  int x;
  const int N = 5;
  extern int q();

  struct local {
    int g() { return x; }        // error: odr-use of automatic variable x
    int h() { return s; }        // OK
    int k() { return ::x; }      // OK
    int l() { return q(); }      // OK
    int m() { return N; }        // OK: not an odr-use
    int* n() { return &N; }      // error: odr-use of automatic variable N
  };
}

local* p = 0;                    // error: local not in scope
```

— *end example*]

1

An enclosing function has no special access to members of the local class; it obeys the usual access rules (Clause 11). Member functions of a local class shall be defined within their class definition, if they are defined at all.

1

If class `X` is a local class a nested class `Y` may be declared in class `X` and later defined in the definition of class `X` or be later defined in the same scope as the definition of class `X`. A class nested within a local class is a local class.

1 A local class shall not have static data members.

9.992 Nested type names [class.nested.type]

1

Type names obey exactly the same scope rules as other names. In particular, type names defined within a class definition cannot be used outside their class without qualification. [*Example:*

```
struct X {
  typedef int I;
  class Y { /* ... */ };
  I a;
};

I b;                             // error
Y c;                             // error
X::Y d;                          // OK
X::I e;                          // OK
```

— *end example*]

10 Derived classes [class.derived]

1 A list of base classes can be specified in a class definition using the notation:

base-clause:
: *base-specifier-list*

base-specifier-list:
base-specifier ...$_{opt}$
base-specifier-list , *base-specifier* ...$_{opt}$

base-specifier:
attribute-specifier-seq$_{opt}$ *base-type-specifier*
attribute-specifier-seq$_{opt}$ `virtual` *access-specifier*$_{opt}$ *base-type-specifier*
attribute-specifier-seq$_{opt}$ *access-specifier* `virtual`$_{opt}$ *base-type-specifier*

class-or-decltype:
nested-name-specifier$_{opt}$ *class-name*
decltype-specifier

base-type-specifier:
class-or-decltype

access-specifier:
`private`
`protected`
`public`

The optional *attribute-specifier-seq* appertains to the *base-specifier*.

2

The type denoted by a *base-type-specifier* shall be a class type that is not an incompletely defined class (Clause 9); this class is called a *direct base class* for the class being defined. During the lookup for a base class name, non-type names are ignored (3.875.1). If the name found is not a *class-name*, the program is ill-formed. A class `B` is a base class of a class `D` if it is a direct base class of `D` or a direct base class of one of `D`'s base classes. A class is an *indirect* base class of another if it is a base class but not a direct base class. A class is said to be (directly or indirectly) *derived* from its (direct or indirect) base classes. [*Note:* See Clause 11 for the meaning of *access-specifier*. — *end note*] Unless redeclared in the derived class, members of a base class are also considered to be members of the derived class. The base class members are said to be *inherited* by the derived class. Inherited members can be referred to in expressions in the same manner as other members of the derived class, unless their names are hidden or ambiguous (10.52). [*Note:* The scope resolution operator `::` (5.398) can be used to refer to a direct or indirect base member explicitly. This allows access to a name that has been redeclared in the derived class. A derived class can itself serve as a base class subject to access control; see 11.43. A pointer to a derived class can be implicitly converted to a pointer to an accessible unambiguous base class (4.579). An lvalue of a derived class type can be bound to a reference to an accessible unambiguous base class (8.2156.1). — *end note*]

1

The *base-specifier-list* specifies the type of the *base class subobjects* contained in an object of the derived class type. [*Example:*

```
struct Base {
  int a, b, c;
};

struct Derived : Base {
```

```
  int b;
};

struct Derived2 : Derived {
  int c;
};
```

Here, an object of class `Derived2` will have a subobject of class `Derived` which in turn will have a subobject of class `Base`. — *end example*]

1 A *base-specifier* followed by an ellipsis is a pack expansion (14.703.1).

2

The order in which the base class subobjects are allocated in the most derived object (1.319) is unspecified. [*Note:* a derived class and its base class subobjects can be represented by a directed acyclic graph (DAG) where an arrow means "directly derived from." A DAG of subobjects is often referred to as a "subobject lattice."

Figure 2 — Directed acyclic graph

1 The arrows need not have a physical representation in memory. — *end note*]

2 [*Note:* Initialization of objects representing base classes can be specified in constructors; see 12.1026.1. — *end note*]

3

[*Note:* A base class subobject might have a layout (3.2235) different from the layout of a most derived object of the same type. A base class subobject might have a polymorphic behavior (12.1483) different from the polymorphic behavior of a most derived object of the same type. A base class subobject may be of zero size (Clause 9); however, two subobjects that have the same class type and that belong to the same most derived object must not be allocated at the same address (5.3247). — *end note*]

10.31 Multiple base classes [class.mi]

1

A class can be derived from any number of base classes. [*Note:* The use of more than one direct base class is often called multiple inheritance. — *end note*] [*Example:*

```
class A { /* ... */ };
class B { /* ... */ };
class C { /* ... */ };
class D : public A, public B, public C { /* ... */ };
```

— *end example*]

1

[*Note:* The order of derivation is not significant except as specified by the semantics of initialization by constructor (12.1026.1), cleanup (12.807), and storage layout (9.194, 11.36). — *end note*]

1

A class shall not be specified as a direct base class of a derived class more than once. [*Note:* A class can be an indirect base class more than once and can be a direct and an indirect base class. There are limited things that can be done with such a class. The non-static data members and member functions of the direct base class cannot be referred to in the scope of the derived class. However, the static members, enumerations and types can be unambiguously referred to. — *end note*] [*Example:*

```
class X { /* ... */ };
class Y : public X, public X { /* ... */ };              // ill-formed

class L { public: int next;  /* ... */ };
class A : public L { /* ... */ };
class B : public L { /* ... */ };
class C : public A, public B { void f(); /* ... */ };    // well-formed
class D : public A, public L { void f(); /* ... */ };    // well-formed
```

— *end example*]

1

A base class specifier that does not contain the keyword `virtual`, specifies a *non-virtual* base class. A base class specifier that contains the keyword `virtual`, specifies a *virtual* base class. For each distinct occurrence of a non-virtual base class in the class lattice of the most derived class, the most derived object (1.319) shall contain a corresponding distinct base class subobject of that type. For each distinct base class that is specified virtual, the most derived object shall contain a single base class subobject of that type. [*Example:* for an object of class type `C`, each distinct occurrence of a (non-virtual) base class `L` in the class lattice of `C` corresponds one-to-one with a distinct `L` subobject within the object of type `C`. Given the class `C` defined above, an object of class `C` will have two subobjects of class `L` as shown below.

Figure 3 — Non-virtual base

1

In such lattices, explicit qualification can be used to specify which subobject is meant. The body of function `C::f` could refer to the member `next` of each `L` subobject:

```
void C::f() { A::next = B::next; }        // well-formed
```

Without the `A::` or `B::` qualifiers, the definition of `C::f` above would be ill-formed because of ambiguity (10.52).

1

For another example,

```
class V { /* ... */ };
class A : virtual public V { /* ... */ };
class B : virtual public V { /* ... */ };
class C : public A, public B { /* ... */ };
```

for an object `c` of class type `C`, a single subobject of type `V` is shared by every base subobject of `c` that has a `virtual` base class of type `V`. Given the class `C` defined above, an object of class `C` will have one subobject of class `V`, as shown below.

Figure 4 — Virtual base

1 A class can have both virtual and non-virtual base classes of a given type.

```
class B { /* ... */ };
class X : virtual public B { /* ... */ };
class Y : virtual public B { /* ... */ };
class Z : public B { /* ... */ };
class AA : public X, public Y, public Z { /* ... */ };
```

For an object of class `AA`, all `virtual` occurrences of base class `B` in the class lattice of `AA` correspond to a single `B` subobject within the object of type `AA`, and every other occurrence of a (non-virtual) base class `B` in the class lattice of `AA` corresponds one-to-one with a distinct `B` subobject within the object of type `AA`. Given the class `AA` defined above, class `AA` has two subobjects of class `B`: `Z`'s `B` and the virtual `B` shared by `X` and `Y`, as shown below.

Figure 5 — Virtual and non-virtual base

— *end example*]

10.52 Member name lookup [class.member.lookup]

1

Member name lookup determines the meaning of a name (*id-expression*) in a class scope (3.760.1). Name lookup can result in an *ambiguity*, in which case the program is ill-formed. For an *id-expression*, name

lookup begins in the class scope of `this`; for a *qualified-id*, name lookup begins in the scope of the *nested-name-specifier*. Name lookup takes place before access control (3.923, Clause 11).

1

The following steps define the result of name lookup for a member name `f` in a class scope `C`.

1

The *lookup set* for `f` in `C`, called $S(f, C)$, consists of two component sets: the *declaration set*, a set of members named `f`; and the *subobject set*, a set of subobjects where declarations of these members (possibly including *using-declarations*) were found. In the declaration set, *using-declarations* are replaced by the set of designated members that are not hidden or overridden by members of the derived class (7.1311.1), and type declarations (including injected-class-names) are replaced by the types they designate. $S(f, C)$ is calculated as follows:

1

If `C` contains a declaration of the name `f`, the declaration set contains every declaration of `f` declared in `C` that satisfies the requirements of the language construct in which the lookup occurs. [*Note:* Looking up a name in an *elaborated-type-specifier* (3.1395.1) or *base-specifier* (Clause 10), for instance, ignores all non-type declarations, while looking up a name in a *nested-name-specifier* (3.1236.1) ignores function, variable, and enumerator declarations. As another example, looking up a name in a *using-declaration* (7.1311.1) includes the declaration of a class or enumeration that would ordinarily be hidden by another declaration of that name in the same scope. — *end note*] If the resulting declaration set is not empty, the subobject set contains `C` itself, and calculation is complete.

1

Otherwise (i.e., `C` does not contain a declaration of `f` or the resulting declaration set is empty), $S(f, C)$ is initially empty. If `C` has base classes, calculate the lookup set for `f` in each direct base class subobject B_i, and merge each such lookup set $S(f, B_i)$ in turn into $S(f, C)$.

1

The following steps define the result of merging lookup set $S(f, B_i)$ into the intermediate $S(f, C)$:

— If each of the subobject members of $S(f, B_i)$ is a base class subobject of at least one of the subobject members of $S(f, C)$, or if $S(f, B_i)$ is empty, $S(f, C)$ is unchanged and the merge is complete. Conversely, if each of the subobject members of $S(f, C)$ is a base class subobject of at least one of the subobject members of $S(f, B_i)$, or if $S(f, C)$ is empty, the new $S(f, C)$ is a copy of $S(f, B_i)$.

— Otherwise, if the declaration sets of $S(f, B_i)$ and $S(f, C)$ differ, the merge is ambiguous: the new $S(f, C)$ is a lookup set with an invalid declaration set and the union of the subobject sets. In subsequent merges, an invalid declaration set is considered different from any other.

— Otherwise, the new $S(f, C)$ is a lookup set with the shared set of declarations and the union of the subobject sets.

1

The result of name lookup for `f` in `C` is the declaration set of $S(f, C)$. If it is an invalid set, the program is ill-formed. [*Example:*

```
struct A { int x; };                    // S(x,A) = { { A::x }, { A } }
struct B { float x; };                  // S(x,B) = { { B::x }, { B } }
struct C: public A, public B { };       // S(x,C) = { invalid, { A in C, B in C } }
struct D: public virtual C { };         // S(x,D) = S(x,C)
struct E: public virtual C { char x; }; // S(x,E) = { { E::x }, { E } }
struct F: public D, public E { };       // S(x,F) = S(x,E)
int main() {
```

```
  F f;
  f.x = 0;                          // OK, lookup finds E::x
}
```

$S(x, F)$ is unambiguous because the `A` and `B` base subobjects of `D` are also base subobjects of `E`, so $S(x, D)$ is discarded in the first merge step. — *end example*]

1

If the name of an overloaded function is unambiguously found, overloading resolution (13.88) also takes place before access control. Ambiguities can often be resolved by qualifying a name with its class name. [*Example:*

```
struct A {
  int f();
};

struct B {
  int f();
};

struct C : A, B {
  int f() { return A::f() + B::f(); }
};
```

— *end example*]

1

[*Note:* A static member, a nested type or an enumerator defined in a base class `T` can unambiguously be found even if an object has more than one base class subobject of type `T`. Two base class subobjects share the non-static member subobjects of their common virtual base classes. — *end note*] [*Example:*

```
struct V {
  int v;
};
struct A {
  int a;
  static int   s;
  enum { e };
};
struct B : A, virtual V { };
struct C : A, virtual V { };
struct D : B, C { };

void f(D* pd) {
  pd->v++;          // OK: only one v (virtual)
  pd->s++;          // OK: only one s (static)
  int i = pd->e;    // OK: only one e (enumerator)
  pd->a++;          // error, ambiguous: two as in D
}
```

— *end example*]

1 [*Note:* When virtual base classes are used, a hidden declaration can be reached along a path through the subobject lattice that does not pass through the hiding declaration. This is not an ambiguity. The identical use with non-virtual base classes is an ambiguity; in that case there is no unique instance of the name that hides all the others. — *end note*] [*Example:*

```
struct V { int f();  int x; };
struct W { int g();  int y; };
struct B : virtual V, W {
  int f();  int x;
  int g();  int y;
};
struct C : virtual V, W { };

struct D : B, C { void glorp(); };
```

Figure 6 — Name lookup

2 [*Note:* The names declared in `V` and the left-hand instance of `W` are hidden by those in `B`, but the names declared in the right-hand instance of `W` are not hidden at all. — *end note*]

```
void D::glorp() {
  x++;              // OK: B::x hides V::x
  f();              // OK: B::f() hides V::f()
  y++;              // error: B::y and C's W::y
  g();              // error: B::g() and C's W::g()
}
```

— *end example*]

3 An explicit or implicit conversion from a pointer to or an expression designating an object of a derived class to a pointer or reference to one of its base classes shall unambiguously refer to a unique object representing the base class. [*Example:*

```
struct V { };
struct A { };
struct B : A, virtual V { };
struct C : A, virtual V { };
struct D : B, C { };

void g() {
  D d;
  B* pb = &d;
  A* pa = &d;       // error, ambiguous: C's A or B's A?
  V* pv = &d;       // OK: only one V subobject
}
```

— *end example*]

4

[*Note:* Even if the result of name lookup is unambiguous, use of a name found in multiple subobjects might still be ambiguous (4.710, 5.1194.1, 11.43). — *end note*] [*Example:*

```
struct B1 {
  void f();
  static void f(int);
  int i;
};
struct B2 {
  void f(double);
};
struct I1: B1 { };
struct I2: B1 { };

struct D: I1, I2, B2 {
  using B1::f;
  using B2::f;
  void g() {
    f();                        // Ambiguous conversion of this
    f(0);                       // Unambiguous (static)
    f(0.0);                     // Unambiguous (only one B2)
    int B1::* mpB1 = &D::i;     // Unambiguous
    int D::* mpD = &D::i;       // Ambiguous conversion
  }
};
```

— *end example*]

10.113 Virtual functions [class.virtual]

1

Virtual functions support dynamic binding and object-oriented programming. A class that declares or inherits a virtual function is called a *polymorphic class*.

1

If a virtual member function `vf` is declared in a class `Base` and in a class `Derived`, derived directly or indirectly from `Base`, a member function `vf` with the same name, parameter-type-list (8.360.1), cv-qualification, and ref-qualifier (or absence of same) as `Base::vf` is declared, then `Derived::vf` is also virtual (whether or not it is so declared) and it *overrides*[112] `Base::vf`. For convenience we say that any virtual function overrides itself. A virtual member function `C::vf` of a class object `S` is a *final overrider* unless the most derived class (1.319) of which `S` is a base class subobject (if any) declares or inherits another member function that overrides `vf`. In a derived class, if a virtual member function of a base class subobject has more than one final overrider the program is ill-formed. [*Example:*

```
struct A {
  virtual void f();
};
struct B : virtual A {
  virtual void f();
};
struct C : B , virtual A {
  using A::f;
};

void foo() {
```

112) A function with the same name but a different parameter list (Clause 13) as a virtual function is not necessarily virtual and does not override. The use of the `virtual` specifier in the declaration of an overriding function is legal but redundant (has empty semantics). Access control (Clause 11) is not considered in determining overriding.

```
  C c;
  c.f();              // calls B::f, the final overrider
  c.C::f();           // calls A::f because of the using-declaration
}
```

— *end example*]

[*Example:*

```
struct A { virtual void f(); };
struct B : A { };
struct C : A { void f(); };
struct D : B, C { };  // OK: A::f and C::f are the final overriders
                      // for the B and C subobjects, respectively
```

— *end example*]

1

[*Note:* A virtual member function does not have to be visible to be overridden, for example,

```
struct B {
  virtual void f();
};
struct D : B {
  void f(int);
};
struct D2 : D {
  void f();
};
```

the function `f(int)` in class `D` hides the virtual function `f()` in its base class `B`; `D::f(int)` is not a virtual function. However, `f()` declared in class `D2` has the same name and the same parameter list as `B::f()`, and therefore is a virtual function that overrides the function `B::f()` even though `B::f()` is not visible in class `D2`. — *end note*]

1

If a virtual function `f` in some class `B` is marked with the *virt-specifier* `final` and in a class `D` derived from `B` a function `D::f` overrides `B::f`, the program is ill-formed. [*Example:*

```
struct B {
  virtual void f() const final;
};

struct D : B {
  void f() const;     // error: D::f attempts to override final B::f
};
```

— *end example*]

1

If a virtual function is marked with the *virt-specifier* `override` and does not override a member function of a base class, the program is ill-formed. [*Example:*

```
struct B {
  virtual void f(int);
};
```

```
struct D : B {
  virtual void f(long) override;  // error: wrong signature overriding B::f
  virtual void f(int) override;   // OK
};
```

— *end example*]

1

Even though destructors are not inherited, a destructor in a derived class overrides a base class destructor declared virtual; see 12.807 and 12.988.

1

The return type of an overriding function shall be either identical to the return type of the overridden function or *covariant* with the classes of the functions. If a function `D::f` overrides a function `B::f`, the return types of the functions are covariant if they satisfy the following criteria:

— both are pointers to classes, both are lvalue references to classes, or both are rvalue references to classes[113]

— the class in the return type of `B::f` is the same class as the class in the return type of `D::f`, or is an unambiguous and accessible direct or indirect base class of the class in the return type of `D::f`

— both pointers or references have the same cv-qualification and the class type in the return type of `D::f` has the same cv-qualification as or less cv-qualification than the class type in the return type of `B::f`.

1

If the class type in the covariant return type of `D::f` differs from that of `B::f`, the class type in the return type of `D::f` shall be complete at the point of declaration of `D::f` or shall be the class type `D`. When the overriding function is called as the final overrider of the overridden function, its result is converted to the type returned by the (statically chosen) overridden function (5.955.1). [*Example:*

```
class B { };
class D : private B { friend class Derived; };
struct Base {
  virtual void vf1();
  virtual void vf2();
  virtual void vf3();
  virtual B*   vf4();
  virtual B*   vf5();
  void f();
};

struct No_good : public Base {
  D*  vf4();        // error: B (base class of D) inaccessible
};

class A;
struct Derived : public Base {
    void vf1();     // virtual and overrides Base::vf1()
    void vf2(int);  // not virtual, hides Base::vf2()
    char vf3();     // error: invalid difference in return type only
    D*  vf4();      // OK: returns pointer to derived class
    A*  vf5();      // error: returns pointer to incomplete class
```

113) Multi-level pointers to classes or references to multi-level pointers to classes are not allowed.

```
    void f();
};

void g() {
  Derived d;
  Base* bp = &d;                // standard conversion:
                                // Derived* to Base*
  bp->vf1();                    // calls Derived::vf1()
  bp->vf2();                    // calls Base::vf2()
  bp->f();                      // calls Base::f() (not virtual)
  B*  p = bp->vf4();            // calls Derived::pf() and converts the
                                // result to B*
  Derived*  dp = &d;
  D*  q = dp->vf4();            // calls Derived::pf() and does not
                                // convert the result to B*
  dp->vf2();                    // ill-formed: argument mismatch
}
```

— *end example*]

1

[*Note:* The interpretation of the call of a virtual function depends on the type of the object for which it is called (the dynamic type), whereas the interpretation of a call of a non-virtual member function depends only on the type of the pointer or reference denoting that object (the static type) (5.955.1). — *end note*]

1

[*Note:* The `virtual` specifier implies membership, so a virtual function cannot be a nonmember (7.94.1) function. Nor can a virtual function be a static member, since a virtual function call relies on a specific object for determining which function to invoke. A virtual function declared in one class can be declared a `friend` in another class. — *end note*]

1

A virtual function declared in a class shall be defined, or declared pure (10.276) in that class, or both; but no diagnostic is required (3.91).

1 [*Example:* here are some uses of virtual functions with multiple base classes:

```
struct A {
  virtual void f();
};

struct B1 : A {                 // note non-virtual derivation
  void f();
};

struct B2 : A {
  void f();
};

struct D : B1, B2 {             // D has two separate A subobjects
};

void foo() {
  D   d;
// A* ap = &d; // would be ill-formed: ambiguous
  B1*  b1p = &d;
```

```
  A*   ap = b1p;
  D*   dp = &d;
  ap->f();                        // calls D::B1::f
  dp->f();                        // ill-formed: ambiguous
}
```

In class `D` above there are two occurrences of class `A` and hence two occurrences of the virtual member function `A::f`. The final overrider of `B1::A::f` is `B1::f` and the final overrider of `B2::A::f` is `B2::f`.

2

The following example shows a function that does not have a unique final overrider:

```
struct A {
  virtual void f();
};

struct VB1 : virtual A {          // note virtual derivation
  void f();
};

struct VB2 : virtual A {
  void f();
};

struct Error : VB1, VB2 {         // ill-formed
};

struct Okay : VB1, VB2 {
  void f();
};
```

Both `VB1::f` and `VB2::f` override `A::f` but there is no overrider of both of them in class `Error`. This example is therefore ill-formed. Class `Okay` is well formed, however, because `Okay::f` is a final overrider.

1 The following example uses the well-formed classes from above.

```
struct VB1a : virtual A {         // does not declare f
};

struct Da : VB1a, VB2 {
};

void foe() {
  VB1a*  vb1ap = new Da;
  vb1ap->f();                     // calls VB2::f
}
```

— *end example*]

2

Explicit qualification with the scope operator (5.398) suppresses the virtual call mechanism. [*Example:*

```
class B { public: virtual void f(); };
class D : public B { public: void f(); };

void D::f() { /* ... */ B::f(); }
```

Here, the function call in `D::f` really does call `B::f` and not `D::f`. — *end example*]

1

A function with a deleted definition (8.706) shall not override a function that does not have a deleted definition. Likewise, a function that does not have a deleted definition shall not override a function with a deleted definition.

10.276 Abstract classes [class.abstract]

1

The abstract class mechanism supports the notion of a general concept, such as a `shape`, of which only more concrete variants, such as `circle` and `square`, can actually be used. An abstract class can also be used to define an interface for which derived classes provide a variety of implementations.

1

An *abstract class* is a class that can be used only as a base class of some other class; no objects of an abstract class can be created except as subobjects of a class derived from it. A class is abstract if it has at least one *pure virtual function*. [*Note:* Such a function might be inherited: see below. — *end note*] A virtual function is specified *pure* by using a *pure-specifier* (9.194) in the function declaration in the class definition. A pure virtual function need be defined only if called with, or as if with (12.807), the *qualified-id* syntax (5.398). [*Example:*

```
class point { /* ... */ };
class shape {                    // abstract class
  point center;
public:
  point where() { return center; }
  void move(point p) { center=p; draw(); }
  virtual void rotate(int) = 0; // pure virtual
  virtual void draw() = 0;      // pure virtual
};
```

— *end example*] [*Note:* A function declaration cannot provide both a *pure-specifier* and a definition — *end note*] [*Example:*

```
struct C {
  virtual void f() = 0 { };     // ill-formed
};
```

— *end example*]

1

An abstract class shall not be used as a parameter type, as a function return type, or as the type of an explicit conversion. Pointers and references to an abstract class can be declared. [*Example:*

```
shape x;                        // error: object of abstract class
shape* p;                       // OK
shape f();                      // error
void g(shape);                  // error
shape& h(shape&);               // OK
```

— *end example*]

1

A class is abstract if it contains or inherits at least one pure virtual function for which the final overrider is pure virtual. [*Example:*

```
class ab_circle : public shape {
  int radius;
public:
  void rotate(int) { }
  // ab_circle::draw() is a pure virtual
};
```

Since `shape::draw()` is a pure virtual function `ab_circle::draw()` is a pure virtual by default. The alternative declaration,

```
class circle : public shape {
  int radius;
public:
  void rotate(int) { }
  void draw();                    // a definition is required somewhere
};
```

would make class `circle` nonabstract and a definition of `circle::draw()` must be provided. — *end example*]

1

[*Note:* An abstract class can be derived from a class that is not abstract, and a pure virtual function may override a virtual function which is not pure. — *end note*]

1

Member functions can be called from a constructor (or destructor) of an abstract class; the effect of making a virtual call (10.113) to a pure virtual function directly or indirectly for the object being created (or destroyed) from such a constructor (or destructor) is undefined.

11 Member access control [class.access]

1

A member of a class can be

— `private`; that is, its name can be used only by members and friends of the class in which it is declared.

— `protected`; that is, its name can be used only by members and friends of the class in which it is declared, by classes derived from that class, and by their friends (see 11.169).

— `public`; that is, its name can be used anywhere without access restriction.

1

A member of a class can also access all the names to which the class has access. A local class of a member function may access the same names that the member function itself may access.[114]

1

Members of a class defined with the keyword `class` are `private` by default. Members of a class defined with the keywords `struct` or `union` are `public` by default. [*Example:*

```
class X {
  int a;            // X::a is private by default
};

struct S {
  int a;            // S::a is public by default
};
```

— *end example*]

1

Access control is applied uniformly to all names, whether the names are referred to from declarations or expressions. [*Note:* Access control applies to names nominated by `friend` declarations (11.94) and *using-declarations* (7.1311.1). — *end note*] In the case of overloaded function names, access control is applied to the function selected by overload resolution. [*Note:* Because access control applies to names, if access control is applied to a typedef name, only the accessibility of the typedef name itself is considered. The accessibility of the entity referred to by the typedef is not considered. For example,

```
class A {
  class B { };
public:
  typedef B BB;
};

void f() {
  A::BB x;          // OK, typedef name A::BB is public
  A::B y;           // access error, A::B is private
}
```

114) Access permissions are thus transitive and cumulative to nested and local classes.

— *end note*]

1

It should be noted that it is *access* to members and base classes that is controlled, not their *visibility*. Names of members are still visible, and implicit conversions to base classes are still considered, when those members and base classes are inaccessible. The interpretation of a given construct is established without regard to access control. If the interpretation established makes use of inaccessible member names or base classes, the construct is ill-formed.

1

All access controls in Clause 11 affect the ability to access a class member name from the declaration of a particular entity, including parts of the declaration preceding the name of the entity being declared and, if the entity is a class, the definitions of members of the class appearing outside the class's *member-specification*. [*Note:* this access also applies to implicit references to constructors, conversion functions, and destructors. — *end note*] [*Example:*

```
class A {
  typedef int I;     // private member
  I f();
  friend I g(I);
  static I x;
  template<int> struct Q;
  template<int> friend struct R;
protected:
    struct B { };
};

A::I A::f() { return 0; }
A::I g(A::I p = A::x);
A::I g(A::I p) { return 0; }
A::I A::x = 0;
template<A::I> struct A::Q { };
template<A::I> struct R { };

struct D: A::B, A { };
```

1

Here, all the uses of `A::I` are well-formed because `A::f`, `A::x`, and `A::Q` are members of class `A` and `g` and `R` are friends of class `A`. This implies, for example, that access checking on the first use of `A::I` must be deferred until it is determined that this use of `A::I` is as the return type of a member of class `A`. Similarly, the use of `A::B` as a *base-specifier* is well-formed because `D` is derived from `A`, so checking of *base-specifier*s must be deferred until the entire *base-specifier-list* has been seen. — *end example*]

1

The names in a default argument (8.545.1) are bound at the point of declaration, and access is checked at that point rather than at any points of use of the default argument. Access checking for default arguments in function templates and in member functions of class templates is performed as described in 14.1644.1.

1 The names in a default *template-argument* (14.97) have their access checked in the context in which they appear rather than at any points of use of the default *template-argument*. [*Example:*

```
class B { };
template <class T> class C {
protected:
  typedef T TT;
```

```
};

template <class U, class V = typename U::TT>
class D : public U { };

D <C<B> >* d;        // access error, C::TT is protected
```

— *end example*]

11.36 Access specifiers [class.access.spec]

1 Member declarations can be labeled by an *access-specifier* (Clause 10):

access-specifier : *member-specification*$_{opt}$

An *access-specifier* specifies the access rules for members following it until the end of the class or until another *access-specifier* is encountered. [*Example:*

```
class X {
  int a;             // X::a is private by default: class used
public:
  int b;             // X::b is public
  int c;             // X::c is public
};
```

— *end example*]

2 Any number of access specifiers is allowed and no particular order is required. [*Example:*

```
struct S {
  int a;             // S::a is public by default: struct used
protected:
  int b;             // S::b is protected
private:
  int c;             // S::c is private
public:
  int d;             // S::d is public
};
```

— *end example*]

3 [*Note:* The effect of access control on the order of allocation of data members is described in 9.194. — *end note*]

4 When a member is redeclared within its class definition, the access specified at its redeclaration shall be the same as at its initial declaration. [*Example:*

```
struct S {
  class A;
  enum E : int;
private:
  class A { };         // error: cannot change access
  enum E: int { e0 }; // error: cannot change access
};
```

— *end example*]

5

[*Note:* In a derived class, the lookup of a base class name will find the injected-class-name instead of the name of the base class in the scope in which it was declared. The injected-class-name might be less accessible than the name of the base class in the scope in which it was declared. — *end note*]

[*Example:*

```
class A { };
class B : private A { };
class C : public B {
  A* p;              // error: injected-class-name A is inaccessible
  ::A* q;            // OK
};
```

— *end example*]

11.43 Accessibility of base classes and base class members [class.access.base]

1

If a class is declared to be a base class (Clause 10) for another class using the `public` access specifier, the `public` members of the base class are accessible as `public` members of the derived class and `protected` members of the base class are accessible as `protected` members of the derived class. If a class is declared to be a base class for another class using the `protected` access specifier, the `public` and `protected` members of the base class are accessible as `protected` members of the derived class. If a class is declared to be a base class for another class using the `private` access specifier, the `public` and `protected` members of the base class are accessible as `private` members of the derived class[115].

1

In the absence of an *access-specifier* for a base class, `public` is assumed when the derived class is defined with the *class-key* `struct` and `private` is assumed when the class is defined with the *class-key* `class`. [*Example:*

```
class B { /* ... */ };
class D1 : private B { /* ... */ };
class D2 : public B { /* ... */ };
class D3 : B { /* ... */ };      // B private by default
struct D4 : public B { /* ... */ };
struct D5 : private B { /* ... */ };
struct D6 : B { /* ... */ };     // B public by default
class D7 : protected B { /* ... */ };
struct D8 : protected B { /* ... */ };
```

Here `B` is a public base of `D2`, `D4`, and `D6`, a private base of `D1`, `D3`, and `D5`, and a protected base of `D7` and `D8`. — *end example*]

1

[*Note:* A member of a private base class might be inaccessible as an inherited member name, but accessible directly. Because of the rules on pointer conversions (4.579) and explicit casts (5.2765), a conversion from a pointer to a derived class to a pointer to an inaccessible base class might be ill-formed if an implicit conversion is used, but well-formed if an explicit cast is used. For example,

```
class B {
public:
  int mi;                    // non-static member
  static int si;             // static member
```

115) As specified previously in Clause 11, private members of a base class remain inaccessible even to derived classes unless `friend` declarations within the base class definition are used to grant access explicitly.

```
};
class D : private B {
};
class DD : public D {
  void f();
};

void DD::f() {
  mi = 3;                       // error: mi is private in D
  si = 3;                       // error: si is private in D
  ::B  b;
  b.mi = 3;                     // OK (b.mi is different from this->mi)
  b.si = 3;                     // OK (b.si is different from this->si)
  ::B::si = 3;                  // OK
  ::B* bp1 = this;              // error: B is a private base class
  ::B* bp2 = (::B*)this;        // OK with cast
  bp2->mi = 3;                  // OK: access through a pointer to B.
}
```

— *end note*]

1

A base class `B` of `N` is *accessible* at R, if

— an invented public member of `B` would be a public member of `N`, or

— R occurs in a member or friend of class `N`, and an invented public member of `B` would be a private or protected member of `N`, or

— R occurs in a member or friend of a class `P` derived from `N`, and an invented public member of `B` would be a private or protected member of `P`, or

— there exists a class `S` such that `B` is a base class of `S` accessible at R and `S` is a base class of `N` accessible at R.

[*Example:*

```
class B {
public:
  int m;
};

class S: private B {
  friend class N;
};

class N: private S {
  void f() {
    B* p = this;     // OK because class S satisfies the fourth condition
                     // above: B is a base class of N accessible in f() because
                     // B is an accessible base class of S and S is an accessible
                     // base class of N.
  }
};
```

— *end example*]

1

If a base class is accessible, one can implicitly convert a pointer to a derived class to a pointer to that base class (4.579, 4.710). [*Note:* It follows that members and friends of a class `X` can implicitly convert an `X*` to a pointer to a private or protected immediate base class of `X`. — *end note*] The access to a member is affected by the class in which the member is named. This naming class is the class in which the member name was looked up and found. [*Note:* This class can be explicit, e.g., when a *qualified-id* is used, or implicit, e.g., when a class member access operator (5.1194.1) is used (including cases where an implicit "`this->`" is added). If both a class member access operator and a *qualified-id* are used to name the member (as in `p->T::m`), the class naming the member is the class denoted by the *nested-name-specifier* of the *qualified-id* (that is, `T`). — *end note*] A member `m` is accessible at the point R when named in class `N` if

— `m` as a member of `N` is public, or

— `m` as a member of `N` is private, and R occurs in a member or friend of class `N`, or

— `m` as a member of `N` is protected, and R occurs in a member or friend of class `N`, or in a member or friend of a class `P` derived from `N`, where `m` as a member of `P` is public, private, or protected, or

— there exists a base class `B` of `N` that is accessible at R, and `m` is accessible at R when named in class `B`. [*Example:*

```
class B;
class A {
private:
  int i;
  friend void f(B*);
};
class B : public A { };
void f(B* p) {
  p->i = 1;          // OK: B* can be implicitly converted to A*,
                     // and f has access to i in A
}
```

— *end example*]

1

If a class member access operator, including an implicit "`this->`," is used to access a non-static data member or non-static member function, the reference is ill-formed if the left operand (considered as a pointer in the "`.`" operator case) cannot be implicitly converted to a pointer to the naming class of the right operand. [*Note:* This requirement is in addition to the requirement that the member be accessible as named. — *end note*]

11.94 Friends [class.friend]

1

A friend of a class is a function or class that is given permission to use the private and protected member names from the class. A class specifies its friends, if any, by way of friend declarations. Such declarations give special access rights to the friends, but they do not make the nominated friends members of the befriending class. [*Example:* the following example illustrates the differences between members and friends:

```
class X {
  int a;
  friend void friend_set(X*, int);
public:
```

```
  void member_set(int);
};

void friend_set(X* p, int i) { p->a = i; }
void X::member_set(int i) { a = i; }

void f() {
  X obj;
  friend_set(&obj,10);
  obj.member_set(10);
}
```

— *end example*]

1

Declaring a class to be a friend implies that the names of private and protected members from the class granting friendship can be accessed in the *base-specifier*s and member declarations of the befriended class. [*Example:*

```
class A {
  class B { };
  friend class X;
};

struct X : A::B {    // OK: A::B accessible to friend
  A::B mx;           // OK: A::B accessible to member of friend
  class Y {
    A::B my;         // OK: A::B accessible to nested member of friend
  };
};
```

— *end example*] [*Example:*

```
class X {
  enum { a=100 };
  friend class Y;
};

class Y {
  int v[X::a];       // OK, Y is a friend of X
};

class Z {
  int v[X::a];       // error: X::a is private
};
```

— *end example*]

A class shall not be defined in a friend declaration. [*Example:*

```
class A {
  friend class B { }; // error: cannot define class in friend declaration
};
```

— *end example*]

1

A `friend` declaration that does not declare a function shall have one of the following forms:

`friend` *elaborated-type-specifier* `;`
`friend` *simple-type-specifier* `;`
`friend` *typename-specifier* `;`

[*Note:* A `friend` declaration may be the *declaration* in a *template-declaration* (Clause 14, 14.755.1). — *end note*] If the type specifier in a `friend` declaration designates a (possibly cv-qualified) class type, that class is declared as a friend; otherwise, the `friend` declaration is ignored. [*Example:*

```
class C;
typedef C Ct;

class X1 {
  friend C;          // OK: class C is a friend
};

class X2 {
  friend Ct;         // OK: class C is a friend
  friend D;          // error: no type-name D in scope
  friend class D;    // OK: elaborated-type-specifier declares new class
};

template <typename T> class R {
  friend T;
};

R<C> rc;             // class C is a friend of R<C>
R<int> Ri;           // OK: "friend int;" is ignored
```

— *end example*]

1

A function first declared in a friend declaration has external linkage (3.1459). Otherwise, the function retains its previous linkage (7.49.1).

1

When a `friend` declaration refers to an overloaded name or operator, only the function specified by the parameter types becomes a friend. A member function of a class `X` can be a friend of a class `Y`. [*Example:*

```
class Y {
  friend char* X::foo(int);
  friend X::X(char);             // constructors can be friends
  friend X::~X();                // destructors can be friends
};
```

— *end example*]

1

A function can be defined in a friend declaration of a class if and only if the class is a non-local class (9.975), the function name is unqualified, and the function has namespace scope. [*Example:*

```
class M {
  friend void f() { }            // definition of global f, a friend of M,
                                 // not the definition of a member function
};
```

— *end example*]

1

Such a function is implicitly `inline`. A `friend` function defined in a class is in the (lexical) scope of the class in which it is defined. A friend function defined outside the class is not (3.952.1).

1 No *storage-class-specifier* shall appear in the *decl-specifier-seq* of a friend declaration.

2

A name nominated by a friend declaration shall be accessible in the scope of the class containing the friend declaration. The meaning of the friend declaration is the same whether the friend declaration appears in the `private`, `protected` or `public` (9.194) portion of the class *member-specification*.

1

Friendship is neither inherited nor transitive. [*Example:*

```
class A {
  friend class B;
  int a;
};

class B {
  friend class C;
};

class C  {
  void f(A* p) {
    p->a++;          // error: C is not a friend of A
                     // despite being a friend of a friend
  }
};

class D : public B  {
  void f(A* p) {
    p->a++;          // error: D is not a friend of A
                     // despite being derived from a friend
  }
};
```

— *end example*]

1

If a friend declaration appears in a local class (9.975) and the name specified is an unqualified name, a prior declaration is looked up without considering scopes that are outside the innermost enclosing non-class scope. For a friend function declaration, if there is no prior declaration, the program is ill-formed. For a friend class declaration, if there is no prior declaration, the class that is specified belongs to the innermost enclosing non-class scope, but if it is subsequently referenced, its name is not found by name lookup until a matching declaration is provided in the innermost enclosing non-class scope. [*Example:*

```
class X;
void a();
void f() {
  class Y;
  extern void b();
  class A {
  friend class X;   // OK, but X is a local class, not ::X
  friend class Y;   // OK
  friend class Z;   // OK, introduces local class Z
```

```
  friend void a();   // error, ::a is not considered
  friend void b();   // OK
  friend void c();   // error
  };
  X* px;             // OK, but ::X is found
  Z* pz;             // error, no Z is found
}
```

— *end example*]

11.169 Protected member access [class.protected]

1

An additional access check beyond those described earlier in Clause 11 is applied when a non-static data member or non-static member function is a protected member of its naming class (11.43)[116] As described earlier, access to a protected member is granted because the reference occurs in a friend or member of some class `C`. If the access is to form a pointer to member (5.1898.1), the *nested-name-specifier* shall denote `C` or a class derived from `C`. All other accesses involve a (possibly implicit) object expression (5.1194.1). In this case, the class of the object expression shall be `C` or a class derived from `C`. [*Example:*

```
class B {
protected:
  int i;
  static int j;
};

class D1 : public B {
};

class D2 : public B {
  friend void fr(B*,D1*,D2*);
  void mem(B*,D1*);
};

void fr(B* pb, D1* p1, D2* p2) {
  pb->i = 1;                    // ill-formed
  p1->i = 2;                    // ill-formed
  p2->i = 3;                    // OK (access through a D2)
  p2->B::i = 4;                 // OK (access through a D2, even though
                                // naming class is B)
  int B::* pmi_B = &B::i;       // ill-formed
  int B::* pmi_B2 = &D2::i;     // OK (type of &D2::i is int B::*)
  B::j = 5;                     // OK (because refers to static member)
  D2::j = 6;                    // OK (because refers to static member)
}

void D2::mem(B* pb, D1* p1) {
  pb->i = 1;                    // ill-formed
  p1->i = 2;                    // ill-formed
  i = 3;                        // OK (access through this)
  B::i = 4;                     // OK (access through this, qualification ignored)
  int B::* pmi_B = &B::i;       // ill-formed
  int B::* pmi_B2 = &D2::i;     // OK
  j = 5;                        // OK (because j refers to static member)
```

116) This additional check does not apply to other members, e.g., static data members or enumerator member constants.

```
  B::j = 6;                    // OK (because B::j refers to static member)
}

void g(B* pb, D1* p1, D2* p2) {
  pb->i = 1;                   // ill-formed
  p1->i = 2;                   // ill-formed
  p2->i = 3;                   // ill-formed
}
```

— *end example*]

11.203 Access to virtual functions [class.access.virt]

1

The access rules (Clause 11) for a virtual function are determined by its declaration and are not affected by the rules for a function that later overrides it. [*Example:*

```
class B {
public:
  virtual int f();
};

class D : public B {
private:
  int f();
};

void f() {
  D d;
  B* pb = &d;
  D* pd = &d;

  pb->f();                     // OK: B::f() is public,
                               // D::f() is invoked
  pd->f();                     // error: D::f() is private
}
```

— *end example*]

1

Access is checked at the call point using the type of the expression used to denote the object for which the member function is called (`B*` in the example above). The access of the member function in the class in which it was defined (`D` in the example above) is in general not known.

11.223 Multiple access [class.paths]

1

If a name can be reached by several paths through a multiple inheritance graph, the access is that of the path that gives most access. [*Example:*

```
class W { public: void f(); };
class A : private virtual W { };
class B : public virtual W { };
class C : public A, public B {
  void f() { W::f(); }         // OK
};
```

1

Since `W::f()` is available to `C::f()` along the public path through `B`, access is allowed. — *end example*]

11.226 Nested classes [class.access.nest]

1

A nested class is a member and as such has the same access rights as any other member. The members of an enclosing class have no special access to members of a nested class; the usual access rules (Clause 11) shall be obeyed. [*Example:*

```
class E {
  int x;
  class B { };

  class I {
    B b;                        // OK: E::I can access E::B
    int y;
    void f(E* p, int i) {
      p->x = i;                 // OK: E::I can access E::x
    }
  };

  int g(I* p) {
    return p->y;                // error: I::y is private
  }
};
```

— *end example*]

12 Special member functions [special]

1

The default constructor (12.30), copy constructor and copy assignment operator (12.1577), move constructor and move assignment operator (12.1577), and destructor (12.807) are *special member functions*. [*Note:* The implementation will implicitly declare these member functions for some class types when the program does not explicitly declare them. The implementation will implicitly define them if they are odr-used (3.91). See 12.30, 12.807 and 12.1577. — *end note*] An implicitly-declared special member function is declared at the closing `}` of the *class-specifier*. Programs shall not define implicitly-declared special member functions.

1 Programs may explicitly refer to implicitly-declared special member functions. [*Example:* a program may explicitly call, take the address of or form a pointer to member to an implicitly-declared special member function.

```
struct A { };                    // implicitly declared A::operator=
struct B : A {
  B& operator=(const B &);
};
B& B::operator=(const B& s) {
  this->A::operator=(s);         // well formed
  return *this;
}
```

— *end example*]

2 [*Note:* The special member functions affect the way objects of class type are created, copied, moved, and destroyed, and how values can be converted to values of other types. Often such special member functions are called implicitly. — *end note*]

3

Special member functions obey the usual access rules (Clause 11). [*Example:* declaring a constructor `protected` ensures that only derived classes and friends can create objects using it. — *end example*]

1

For a class, its non-static data members, its non-virtual direct base classes, and, if the class is not abstract (10.276), its virtual base classes are called its *potentially constructed subobjects*.

12.30 Constructors [class.ctor]

1

Constructors do not have names. A declaration of a constructor uses a function declarator (8.360.1) of the form

ptr-declarator (*parameter-declaration-clause*) *exception-specification*$_{opt}$ *attribute-specifier-seq*$_{opt}$

where the *ptr-declarator* consists solely of an *id-expression*, an optional *attribute-specifier-seq*, and optional surrounding parentheses, and the *id-expression* has one of the following forms:

— in a *member-declaration* that belongs to the *member-specification* of a class but is not a friend declaration (11.94), the *id-expression* is the injected-class-name (Clause 9) of the immediately-enclosing class;

— in a *member-declaration* that belongs to the *member-specification* of a class template but is not a friend declaration, the *id-expression* is a *class-name* that names the current instantiation (14.1319.0.1) of the immediately-enclosing class template; or

— in a declaration at namespace scope or in a friend declaration, the *id-expression* is a *qualified-id* that names a constructor (3.1282.0.1).

The *class-name* shall not be a *typedef-name*. In a constructor declaration, each *decl-specifier* in the optional *decl-specifier-seq* shall be `friend`, `inline`, `explicit`, or `constexpr`. [*Example:*

```
struct S {
  S();                // declares the constructor
};

S::S() { }            // defines the constructor
```

— *end example*]

1

A constructor is used to initialize objects of its class type. Because constructors do not have names, they are never found during name lookup; however an explicit type conversion using the functional notation (5.1108.1) will cause a constructor to be called to initialize an object. [*Note:* For initialization of objects of class type see 12.1011. — *end note*]

1

A constructor can be invoked for a `const`, `volatile` or `const volatile` object. `const` and `volatile` semantics (7.567.0.1) are not applied on an object under construction. They come into effect when the constructor for the most derived object (1.319) ends.

1

A *default* constructor for a class `X` is a constructor of class `X` that can be called without an argument. If there is no user-declared constructor for class `X`, a constructor having no parameters is implicitly declared as defaulted (8.706). An implicitly-declared default constructor is an `inline public` member of its class. A defaulted default constructor for class `X` is defined as deleted if:

— `X` is a union-like class that has a variant member with a non-trivial default constructor,

— any non-static data member with no *brace-or-equal-initializer* is of reference type,

— any non-variant non-static data member of const-qualified type (or array thereof) with no *brace-or-equal-initializer* does not have a user-provided default constructor,

— `X` is a union and all of its variant members are of const-qualified type (or array thereof),

— `X` is a non-union class and all members of any anonymous union member are of const-qualified type (or array thereof),

— any potentially constructed subobject, except for a non-static data member with a *brace-or-equal-initializer*, has class type `M` (or array thereof) and either `M` has no default constructor or overload resolution (13.88) as applied to `M`'s default constructor results in an ambiguity or in a function that is deleted or inaccessible from the defaulted default constructor, or

— any potentially constructed subobject has a type with a destructor that is deleted or inaccessible from the defaulted default constructor.

A default constructor is trivial if it is not user-provided and if:

— its class has no virtual functions (10.113) and no virtual base classes (10.31), and

— no non-static data member of its class has a *brace-or-equal-initializer*, and

— all the direct base classes of its class have trivial default constructors, and

— for all the non-static data members of its class that are of class type (or array thereof), each such class has a trivial default constructor.

Otherwise, the default constructor is *non-trivial*.

1

A default constructor that is defaulted and not defined as deleted is *implicitly defined* when it is odr-used (3.91) to create an object of its class type (1.319) or when it is explicitly defaulted after its first declaration. The implicitly-defined default constructor performs the set of initializations of the class that would be performed by a user-written default constructor for that class with no *ctor-initializer* (12.1026.1) and an empty *compound-statement*. If that user-written default constructor would be ill-formed, the program is ill-formed. If that user-written default constructor would satisfy the requirements of a `constexpr` constructor (7.328.1), the implicitly-defined default constructor is `constexpr`. Before the defaulted default constructor for a class is implicitly defined, all the non-user-provided default constructors for its base classes and its non-static data members shall have been implicitly defined. [*Note:* An implicitly-declared default constructor has an *exception-specification* (15.228). An explicitly-defaulted definition might have an implicit *exception-specification,* see 8.706. — *end note*]

1

Default constructors are called implicitly to create class objects of static, thread, or automatic storage duration (3.2242.1, 3.2291.1, 3.2301.1) defined without an initializer (8.821), are called to create class objects of dynamic storage duration (3.2331.1) created by a *new-expression* in which the *new-initializer* is omitted (5.2221.1), or are called when the explicit type conversion syntax (5.1108.1) is used. A program is ill-formed if the default constructor for an object is implicitly used and the constructor is not accessible (Clause 11).

1 [*Note:* 12.1026.1 describes the order in which constructors for base classes and non-static data members are called and describes how arguments can be specified for the calls to these constructors. — *end note*]

2

A `return` statement in the body of a constructor shall not specify a return value. The address of a constructor shall not be taken.

1

A functional notation type conversion (5.1108.1) can be used to create new objects of its type. [*Note:* The syntax looks like an explicit call of the constructor. — *end note*] [*Example:*

```
complex zz = complex(1,2.3);
cprint( complex(7.8,1.2) );
```

— *end example*]

1 An object created in this way is unnamed. [*Note:* 12.306 describes the lifetime of temporary objects. — *end note*] [*Note:* Explicit constructor calls do not yield lvalues, see 3.3673. — *end note*]

2 [*Note:* some language constructs have special semantics when used during construction; see 12.1026.1 and 12.1483. — *end note*]

3

During the construction of a `const` object, if the value of the object or any of its subobjects is accessed through a glvalue that is not obtained, directly or indirectly, from the constructor's `this` pointer, the value of the object or subobject thus obtained is unspecified. [*Example:*

```
struct C;
void no_opt(C*);

struct C {
  int c;
  C() : c(0) { no_opt(this); }
};

const C cobj;

void no_opt(C* cptr) {
  int i = cobj.c * 100;          // value of cobj.c is unspecified
  cptr->c = 1;
  cout << cobj.c * 100           // value of cobj.c is unspecified
       << '\n';
}
```

— *end example*]

12.306 Temporary objects [class.temporary]

1

Temporaries of class type are created in various contexts: binding a reference to a prvalue (8.2156.1), returning a prvalue (6.270.2), a conversion that creates a prvalue (4.127, 5.1443.1, 5.1871.1, 5.2765), throwing an exception (15.7), and in some initializations (8.821). [*Note:* The lifetime of exception objects is described in 15.7. — *end note*] Even when the creation of the temporary object is unevaluated (Clause 5) or otherwise avoided (12.1577), all the semantic restrictions shall be respected as if the temporary object had been created and later destroyed. [*Note:* This includes accessibility (11) and whether it is deleted, for the constructor selected and for the destructor. However, in the special case of a function call used as the operand of a *decltype-specifier* (5.955.1), no temporary is introduced, so the foregoing does not apply to the prvalue of any such function call. — *end note*]

1

[*Example:* Consider the following code:

```
class X {
public:
  X(int);
  X(const X&);
  X& operator=(const X&);
  ~X();
};

class Y {
public:
  Y(int);
  Y(Y&&);
  ~Y();
};

X f(X);
Y g(Y);
```

```
void h() {
  X a(1);
  X b = f(X(2));
  Y c = g(Y(3));
  a = f(a);
}
```

An implementation might use a temporary in which to construct `X(2)` before passing it to `f()` using `X`'s copy constructor; alternatively, `X(2)` might be constructed in the space used to hold the argument. Likewise, an implementation might use a temporary in which to construct `Y(3)` before passing it to `g()` using `Y`'s move constructor; alternatively, `Y(3)` might be constructed in the space used to hold the argument. Also, a temporary might be used to hold the result of `f(X(2))` before copying it to `b` using `X`'s copy constructor; alternatively, `f()`'s result might be constructed in `b`. Likewise, a temporary might be used to hold the result of `g(Y(3))` before moving it to `c` using `Y`'s move constructor; alternatively, `g()`'s result might be constructed in `c`. On the other hand, the expression `a=f(a)` requires a temporary for the result of `f(a)`, which is then assigned to `a`. — *end example*]

1

When an implementation introduces a temporary object of a class that has a non-trivial constructor (12.30, 12.1577), it shall ensure that a constructor is called for the temporary object. Similarly, the destructor shall be called for a temporary with a non-trivial destructor (12.807). Temporary objects are destroyed as the last step in evaluating the full-expression (1.430) that (lexically) contains the point where they were created. This is true even if that evaluation ends in throwing an exception. The value computations and side effects of destroying a temporary object are associated only with the full-expression, not with any specific subexpression.

1

There are two contexts in which temporaries are destroyed at a different point than the end of the full-expression. The first context is when a default constructor is called to initialize an element of an array. If the constructor has one or more default arguments, the destruction of every temporary created in a default argument is sequenced before the construction of the next array element, if any.

1

The second context is when a reference is bound to a temporary.[117] The temporary to which the reference is bound or the temporary that is the complete object of a subobject to which the reference is bound persists for the lifetime of the reference except:

— A temporary bound to a reference member in a constructor's *ctor-initializer* (12.1026.1) persists until the constructor exits.

— A temporary bound to a reference parameter in a function call (5.955.1) persists until the completion of the full-expression containing the call.

— The lifetime of a temporary bound to the returned value in a function return statement (6.270.2) is not extended; the temporary is destroyed at the end of the full-expression in the return statement.

— A temporary bound to a reference in a *new-initializer* (5.2221.1) persists until the completion of the full-expression containing the *new-initializer*. [*Example:*

```
struct S { int mi; const std::pair<int,int>& mp; };
S a { 1, {2,3} };
S* p = new S{ 1, {2,3} };    // Creates dangling reference
```

117) The same rules apply to initialization of an `initializer_list` object (8.2435.1) with its underlying temporary array

— *end example*] [*Note:* This may introduce a dangling reference, and implementations are encouraged to issue a warning in such a case. — *end note*]

The destruction of a temporary whose lifetime is not extended by being bound to a reference is sequenced before the destruction of every temporary which is constructed earlier in the same full-expression. If the lifetime of two or more temporaries to which references are bound ends at the same point, these temporaries are destroyed at that point in the reverse order of the completion of their construction. In addition, the destruction of temporaries bound to references shall take into account the ordering of destruction of objects with static, thread, or automatic storage duration (3.2242.1, 3.2291.1, 3.2301.1); that is, if `obj1` is an object with the same storage duration as the temporary and created before the temporary is created the temporary shall be destroyed before `obj1` is destroyed; if `obj2` is an object with the same storage duration as the temporary and created after the temporary is created the temporary shall be destroyed after `obj2` is destroyed. [*Example:*

```
struct S {
  S();
  S(int);
  friend S operator+(const S&, const S&);
  ~S();
};
S obj1;
const S& cr = S(16)+S(23);
S obj2;
```

the expression `S(16) + S(23)` creates three temporaries: a first temporary `T1` to hold the result of the expression `S(16)`, a second temporary `T2` to hold the result of the expression `S(23)`, and a third temporary `T3` to hold the result of the addition of these two expressions. The temporary `T3` is then bound to the reference `cr`. It is unspecified whether `T1` or `T2` is created first. On an implementation where `T1` is created before `T2`, `T2` shall be destroyed before `T1`. The temporaries `T1` and `T2` are bound to the reference parameters of `operator+`; these temporaries are destroyed at the end of the full-expression containing the call to `operator+`. The temporary `T3` bound to the reference `cr` is destroyed at the end of `cr`'s lifetime, that is, at the end of the program. In addition, the order in which `T3` is destroyed takes into account the destruction order of other objects with static storage duration. That is, because `obj1` is constructed before `T3`, and `T3` is constructed before `obj2`, `obj2` shall be destroyed before `T3`, and `T3` shall be destroyed before `obj1`. — *end example*]

12.659 Conversions [class.conv]

1

Type conversions of class objects can be specified by constructors and by conversion functions. These conversions are called *user-defined conversions* and are used for implicit type conversions (Clause 4), for initialization (8.821), and for explicit type conversions (5.2765, 5.1443.1).

1

User-defined conversions are applied only where they are unambiguous (10.52, 12.742.1). Conversions obey the access control rules (Clause 11). Access control is applied after ambiguity resolution (3.923).

1

[*Note:* See 13.88 for a discussion of the use of conversions in function calls as well as examples below. — *end note*]

1

At most one user-defined conversion (constructor or conversion function) is implicitly applied to a single value.

[*Example:*

```
struct X {
  operator int();
};

struct Y {
  operator X();
};

Y a;
int b = a;          // error
                    // a.operator X().operator int() not tried
int c = X(a);       // OK: a.operator X().operator int()
```

— *end example*]

1

User-defined conversions are used implicitly only if they are unambiguous. A conversion function in a derived class does not hide a conversion function in a base class unless the two functions convert to the same type. Function overload resolution (13.562.1) selects the best conversion function to perform the conversion. [*Example:*

```
struct X {
  operator int();
};

struct Y : X {
    operator char();
};

void f(Y& a) {
  if (a) {          // ill-formed:
                    // X::operator int() or Y::operator char()
  }
}
```

— *end example*]

12.708.1 Conversion by constructor [class.conv.ctor]

1

A constructor declared without the *function-specifier* `explicit` specifies a conversion from the types of its parameters to the type of its class. Such a constructor is called a *converting constructor*. [*Example:*

```
struct X {
    X(int);
    X(const char*, int =0);
    X(int, int);
};

void f(X arg) {
  X a = 1;          // a = X(1)
  X b = "Jessie";   // b = X("Jessie",0)
  a = 2;            // a = X(2)
  f(3);             // f(X(3))
  f({1, 2});        // f(X(1,2))
}
```

— *end example*]

1

An explicit constructor constructs objects just like non-explicit constructors, but does so only where the direct-initialization syntax (8.821) or where casts (5.1443.1, 5.2765) are explicitly used. A default constructor may be an explicit constructor; such a constructor will be used to perform default-initialization or value-initialization (8.821). [*Example:*

```
struct Z {
  explicit Z();
  explicit Z(int);
  explicit Z(int, int);
};

Z a;                          // OK: default-initialization performed
Z a1 = 1;                     // error: no implicit conversion
Z a3 = Z(1);                  // OK: direct initialization syntax used
Z a2(1);                      // OK: direct initialization syntax used
Z* p = new Z(1);              // OK: direct initialization syntax used
Z a4 = (Z)1;                  // OK: explicit cast used
Z a5 = static_cast<Z>(1);     // OK: explicit cast used
Z a6 = { 3, 4 };              // error: no implicit conversion
```

— *end example*]

1

A non-explicit copy/move constructor (12.1577) is a converting constructor. An implicitly-declared copy/-move constructor is not an explicit constructor; it may be called for implicit type conversions.

12.742.1 Conversion functions [class.conv.fct]

1

A member function of a class `X` having no parameters with a name of the form

conversion-function-id:
`operator` *conversion-type-id*

conversion-type-id:
type-specifier-seq conversion-declarator$_{opt}$

conversion-declarator:
ptr-operator conversion-declarator$_{opt}$

specifies a conversion from `X` to the type specified by the *conversion-type-id*. Such functions are called conversion functions. No return type can be specified. If a conversion function is a member function, the type of the conversion function (8.360.1) is "function taking no parameter returning *conversion-type-id*". A conversion function is never used to convert a (possibly cv-qualified) object to the (possibly cv-qualified) same object type (or a reference to it), to a (possibly cv-qualified) base class of that type (or a reference to it), or to (possibly cv-qualified) void.[118]

[*Example:*

```
struct X {
  operator int();
};
```

118) These conversions are considered as standard conversions for the purposes of overload resolution (13.779.0.1, 13.870.0.0.1) and therefore initialization (8.821) and explicit casts (5.1443.1). A conversion to `void` does not invoke any conversion function (5.1443.1). Even though never directly called to perform a conversion, such conversion functions can be declared and can potentially be reached through a call to a virtual conversion function in a base class.

```
void f(X a) {
  int i = int(a);
  i = (int)a;
  i = a;
}
```

In all three cases the value assigned will be converted by `X::operator int()`. — *end example*]

1

A conversion function may be explicit (7.94.1), in which case it is only considered as a user-defined conversion for direct-initialization (8.821). Otherwise, user-defined conversions are not restricted to use in assignments and initializations. [*Example:*

```
class Y { };
struct Z {
  explicit operator Y() const;
};

void h(Z z) {
  Y y1(z);          // OK: direct-initialization
  Y y2 = z;         // ill-formed: copy-initialization
  Y y3 = (Y)z;      // OK: cast notation
}

void g(X a, X b) {
  int i = (a) ? 1+a : 0;
  int j = (a&&b) ? a+b : i;
  if (a) {
  }
}
```

— *end example*]

1

The *conversion-type-id* shall not represent a function type nor an array type. The *conversion-type-id* in a *conversion-function-id* is the longest possible sequence of *conversion-declarator*s. [*Note:* This prevents ambiguities between the declarator operator * and its expression counterparts. [*Example:*

```
&ac.operator int*i; // syntax error:
                    // parsed as: &(ac.operator int *)i
                    // not as: &(ac.operator int)*i
```

The `*` is the pointer declarator and not the multiplication operator. — *end example*] — *end note*]

1 Conversion functions are inherited.

2 Conversion functions can be virtual.

3 Conversion functions cannot be declared `static`.

12.807 Destructors [class.dtor]

1

A declaration of a destructor uses a function declarator (8.360.1) of the form

ptr-declarator (*parameter-declaration-clause*) *exception-specification*$_{opt}$ *attribute-specifier-seq*$_{opt}$

where the *ptr-declarator* consists solely of an *id-expression*, an optional *attribute-specifier-seq*, and optional surrounding parentheses, and the *id-expression* has one of the following forms:

— in a *member-declaration* that belongs to the *member-specification* of a class but is not a friend declaration (11.94), the *id-expression* is `~`*class-name* and the *class-name* is the injected-class-name (Clause 9) of the immediately-enclosing class;

— in a *member-declaration* that belongs to the *member-specification* of a class template but is not a friend declaration, the *id-expression* is `~`*class-name* and the *class-name* names the current instantiation (14.1319.0.1) of the immediately-enclosing class template; or

— in a declaration at namespace scope or in a friend declaration, the *id-expression* is *nested-name-specifier* `~`*class-name* and the *class-name* names the same class as the *nested-name-specifier*.

The *class-name* shall not be a *typedef-name*. A destructor shall take no arguments (8.360.1). In a destructor declaration, each *decl-specifier* of the optional *decl-specifier-seq* shall be `friend`, `inline`, or `virtual`.

1

A destructor is used to destroy objects of its class type. The address of a destructor shall not be taken. A destructor can be invoked for a `const`, `volatile` or `const volatile` object. `const` and `volatile` semantics (7.567.0.1) are not applied on an object under destruction. They stop being in effect when the destructor for the most derived object (1.319) starts.

1

A declaration of a destructor that does not have an *exception-specification* is implicitly considered to have the same *exception-specification* as an implicit declaration (15.228).

1

If a class has no user-declared destructor, a destructor is implicitly declared as defaulted (8.706). An implicitly-declared destructor is an `inline public` member of its class.

1

A defaulted destructor for a class `X` is defined as deleted if:

— `X` is a union-like class that has a variant member with a non-trivial destructor,

— any potentially constructed subobject has class type `M` (or array thereof) and `M` has a deleted destructor or a destructor that is inaccessible from the defaulted destructor,

— or, for a virtual destructor, lookup of the non-array deallocation function results in an ambiguity or in a function that is deleted or inaccessible from the defaulted destructor.

A destructor is trivial if it is not user-provided and if:

— the destructor is not `virtual`,

— all of the direct base classes of its class have trivial destructors, and

— for all of the non-static data members of its class that are of class type (or array thereof), each such class has a trivial destructor.

Otherwise, the destructor is *non-trivial*.

1

A destructor that is defaulted and not defined as deleted is *implicitly defined* when it is odr-used (3.91) to destroy an object of its class type (3.2235) or when it is explicitly defaulted after its first declaration.

1 Before the defaulted destructor for a class is implicitly defined, all the non-user-provided destructors for its base classes and its non-static data members shall have been implicitly defined.

2

After executing the body of the destructor and destroying any automatic objects allocated within the body, a destructor for class `X` calls the destructors for `X`'s direct non-variant non-static data members, the destructors for `X`'s direct base classes and, if `X` is the type of the most derived class (12.1026.1), its destructor calls the destructors for `X`'s virtual base classes. All destructors are called as if they were referenced with a qualified name, that is, ignoring any possible virtual overriding destructors in more derived classes. Bases and members are destroyed in the reverse order of the completion of their constructor (see 12.1026.1). A `return` statement (6.270.2) in a destructor might not directly return to the caller; before transferring control to the caller, the destructors for the members and bases are called. Destructors for elements of an array are called in reverse order of their construction (see 12.1011).

1

A destructor can be declared `virtual` (10.113) or pure `virtual` (10.276); if any objects of that class or any derived class are created in the program, the destructor shall be defined. If a class has a base class with a virtual destructor, its destructor (whether user- or implicitly-declared) is virtual.

1 [*Note:* some language constructs have special semantics when used during destruction; see 12.1483. — *end note*]

2

A destructor is invoked implicitly

— for a constructed object with static storage duration (3.2242.1) at program termination (3.2200.1),

— for a constructed object with thread storage duration (3.2291.1) at thread exit,

— for a constructed object with automatic storage duration (3.2301.1) when the block in which an object is created exits (6.419),

— for a constructed temporary object when its lifetime ends (12.306).

In each case, the context of the invocation is the context of the construction of the object. A destructor is also invoked implicitly through use of a *delete-expression* (5.2455.1) for a constructed object allocated by a *new-expression* (5.2221.1); the context of the invocation is the *delete-expression*. [*Note:* An array of class type contains several subobjects for each of which the destructor is invoked. — *end note*] A destructor can also be invoked explicitly. A destructor is *potentially invoked* if it is invoked or as specified in 5.2221.1 and 12.1026.1. A program is ill-formed if a destructor that is potentially invoked is deleted or not accessible from the context of the invocation.

1

At the point of definition of a virtual destructor (including an implicit definition (12.1577)), the non-array deallocation function is looked up in the scope of the destructor's class (10.52), and, if no declaration is found, the function is looked up in the global scope. If the result of this lookup is ambiguous or inaccessible, or if the lookup selects a placement deallocation function or a function with a deleted definition (8.706), the program is ill-formed. [*Note:* This assures that a deallocation function corresponding to the dynamic type of an object is available for the *delete-expression* (12.988). — *end note*]

1

In an explicit destructor call, the destructor name appears as a `~` followed by a *type-name* or *decltype-specifier* that denotes the destructor's class type. The invocation of a destructor is subject to the usual rules for member functions (9.401); that is, if the object is not of the destructor's class type and not of a class derived from the destructor's class type (including when the destructor is invoked via a null pointer value),

the program has undefined behavior. [*Note:* invoking `delete` on a null pointer does not call the destructor; see 5.2455.1. — *end note*] [*Example:*

```
struct B {
  virtual ~B() { }
};
struct D : B {
  ~D() { }
};

D D_object;
typedef B B_alias;
B* B_ptr = &D_object;

void f() {
  D_object.B::~B();              // calls B's destructor
  B_ptr->~B();                   // calls D's destructor
  B_ptr->~B_alias();             // calls D's destructor
  B_ptr->B_alias::~B();          // calls B's destructor
  B_ptr->B_alias::~B_alias();    // calls B's destructor
}
```

— *end example*] [*Note:* An explicit destructor call must always be written using a member access operator (5.1194.1) or a qualified-id (5.398); in particular, the *unary-expression* `~X()` in a member function is not an explicit destructor call (5.1898.1). — *end note*]

1

[*Note:* explicit calls of destructors are rarely needed. One use of such calls is for objects placed at specific addresses using a *new-expression* with the placement option. Such use of explicit placement and destruction of objects can be necessary to cope with dedicated hardware resources and for writing memory management facilities. For example,

```
void* operator new(std::size_t, void* p) { return p; }
struct X {
  X(int);
  ~X();
};
void f(X* p);

void g() {                       // rare, specialized use:
  char* buf = new char[sizeof(X)];
  X* p = new(buf) X(222);        // use buf[] and initialize
  f(p);
  p->X::~X();                    // cleanup
}
```

— *end note*]

1

Once a destructor is invoked for an object, the object no longer exists; the behavior is undefined if the destructor is invoked for an object whose lifetime has ended (3.2563). [*Example:* if the destructor for an automatic object is explicitly invoked, and the block is subsequently left in a manner that would ordinarily invoke implicit destruction of the object, the behavior is undefined. — *end example*]

1

[*Note:* the notation for explicit call of a destructor can be used for any scalar type name (5.1181.1). Allowing this makes it possible to write code without having to know if a destructor exists for a given type. For example,

```
typedef int I;
I* p;
p->I::~I();
```

— *end note*]

12.988 Free store [class.free]

1

Any allocation function for a class `T` is a static member (even if not explicitly declared `static`).

1 [*Example:*

```
class Arena;
struct B {
  void* operator new(std::size_t, Arena*);
};
struct D1 : B {
};

Arena*  ap;
void foo(int i) {
  new (ap) D1;       // calls B::operator new(std::size_t, Arena*)
  new D1[i];         // calls ::operator new[](std::size_t)
  new D1;            // ill-formed: ::operator new(std::size_t) hidden
}
```

— *end example*]

2

When an object is deleted with a *delete-expression* (5.2455.1), a *deallocation function* (`operator delete()` for non-array objects or `operator delete[]()` for arrays) is (implicitly) called to reclaim the storage occupied by the object (3.2428.0.1).

1

Class-specific deallocation function lookup is a part of general deallocation function lookup (5.2455.1) and occurs as follows. If the *delete-expression* is used to deallocate a class object whose static type has a virtual destructor, the deallocation function is the one selected at the point of definition of the dynamic type's virtual destructor (12.807).[119] Otherwise, if the *delete-expression* is used to deallocate an object of class `T` or array thereof, the static and dynamic types of the object shall be identical and the deallocation function's name is looked up in the scope of `T`. If this lookup fails to find the name, general deallocation function lookup (5.2455.1) continues. If the result of the lookup is ambiguous or inaccessible, or if the lookup selects a placement deallocation function, the program is ill-formed.

1

Any deallocation function for a class `X` is a static member (even if not explicitly declared `static`). [*Example:*

```
class X {
  void operator delete(void*);
  void operator delete[](void*, std::size_t);
```

119) A similar provision is not needed for the array version of `operator delete` because 5.2455.1 requires that in this situation, the static type of the object to be deleted be the same as its dynamic type.

```
};

class Y {
  void operator delete(void*, std::size_t);
  void operator delete[](void*);
};
```

— *end example*]

1

Since member allocation and deallocation functions are `static` they cannot be virtual. [*Note:* however, when the *cast-expression* of a *delete-expression* refers to an object of class type, because the deallocation function actually called is looked up in the scope of the class that is the dynamic type of the object, if the destructor is virtual, the effect is the same. For example,

```
struct B {
  virtual ~B();
  void operator delete(void*, std::size_t);
};

struct D : B {
  void operator delete(void*);
};

void f() {
  B* bp = new D;
  delete bp;        //1: uses D::operator delete(void*)
}
```

Here, storage for the non-array object of class `D` is deallocated by `D::operator delete()`, due to the virtual destructor. — *end note*] [*Note:* Virtual destructors have no effect on the deallocation function actually called when the *cast-expression* of a *delete-expression* refers to an array of objects of class type. For example,

```
struct B {
  virtual ~B();
  void operator delete[](void*, std::size_t);
};

struct D : B {
  void operator delete[](void*, std::size_t);
};

void f(int i) {
  D* dp = new D[i];
  delete [] dp;     // uses D::operator delete[](void*, std::size_t)
  B* bp = new D[i];
  delete[] bp;      // undefined behavior
}
```

— *end note*]

1 Access to the deallocation function is checked statically. Hence, even though a different one might actually be executed, the statically visible deallocation function is required to be accessible. [*Example:* for the call on line //1 above, if `B::operator delete()` had been `private`, the delete expression would have been ill-formed. — *end example*]

2 [*Note:* If a deallocation function has no explicit *exception-specification*, it is treated as if it were specified with `noexcept(true)` (15.228). — *end note*]

12.1011 Initialization [class.init]

1

When no initializer is specified for an object of (possibly cv-qualified) class type (or array thereof), or the initializer has the form `()`, the object is initialized as specified in 8.821.

1

An object of class type (or array thereof) can be explicitly initialized; see 12.1021.1 and 12.1026.1.

1

When an array of class objects is initialized (either explicitly or implicitly) and the elements are initialized by constructor, the constructor shall be called for each element of the array, following the subscript order; see 8.251.1. [*Note:* Destructors for the array elements are called in reverse order of their construction. — *end note*]

12.1021.1 Explicit initialization [class.expl.init]

1

An object of class type can be initialized with a parenthesized *expression-list*, where the *expression-list* is construed as an argument list for a constructor that is called to initialize the object. Alternatively, a single *assignment-expression* can be specified as an *initializer* using the `=` form of initialization. Either direct-initialization semantics or copy-initialization semantics apply; see 8.821. [*Example:*

```
struct complex {
  complex();
  complex(double);
  complex(double,double);
};

complex sqrt(complex,complex);

complex a(1);                   // initialize by a call of
                                // complex(double)
complex b = a;                  // initialize by a copy of a
complex c = complex(1,2);       // construct complex(1,2)
                                // using complex(double,double)
                                // copy/move it into c
complex d = sqrt(b,c);          // call sqrt(complex,complex)
                                // and copy/move the result into d
complex e;                      // initialize by a call of
                                // complex()
complex f = 3;                  // construct complex(3) using
                                // complex(double)
                                // copy/move it into f
complex g = { 1, 2 };           // initialize by a call of
                                // complex(double, double)
```

— *end example*] [*Note:* overloading of the assignment operator (13.1178.1) has no effect on initialization. — *end note*]

1

An object of class type can also be initialized by a *braced-init-list*. List-initialization semantics apply; see 8.821 and 8.2435.1. [*Example:*

```
complex v[6] = { 1, complex(1,2), complex(), 2 };
```

Here, `complex::complex(double)` is called for the initialization of `v[0]` and `v[3]`, `complex::complex(double, double)` is called for the initialization of `v[1]`, `complex::complex()` is called for the initialization `v[2]`, `v[4]`, and `v[5]`. For another example,

```
struct X {
  int i;
  float f;
  complex c;
} x = { 99, 88.8, 77.7 };
```

Here, `x.i` is initialized with 99, `x.f` is initialized with 88.8, and `complex::complex(double)` is called for the initialization of `x.c`. — *end example*] [*Note:* Braces can be elided in the *initializer-list* for any aggregate, even if the aggregate has members of a class type with user-defined type conversions; see 8.1817.1. — *end note*]

1

[*Note:* If `T` is a class type with no default constructor, any declaration of an object of type `T` (or array thereof) is ill-formed if no *initializer* is explicitly specified (see 12.1011 and 8.821). — *end note*]

1 [*Note:* the order in which objects with static or thread storage duration are initialized is described in 3.1937.1 and 6.419. — *end note*]

12.1026.1 Initializing bases and members [class.base.init]

1

In the definition of a constructor for a class, initializers for direct and virtual base subobjects and non-static data members can be specified by a *ctor-initializer*, which has the form

ctor-initializer:
: *mem-initializer-list*
mem-initializer-list:
mem-initializer ...$_{opt}$
mem-initializer ...$_{opt}$, *mem-initializer-list*
mem-initializer:
mem-initializer-id (*expression-list*$_{opt}$)
mem-initializer-id braced-init-list
mem-initializer-id:
class-or-decltype
identifier

1

In a *mem-initializer-id* an initial unqualified *identifier* is looked up in the scope of the constructor's class and, if not found in that scope, it is looked up in the scope containing the constructor's definition. [*Note:* If the constructor's class contains a member with the same name as a direct or virtual base class of the class, a *mem-initializer-id* naming the member or base class and composed of a single identifier refers to the class member. A *mem-initializer-id* for the hidden base class may be specified using a qualified name. — *end note*] Unless the *mem-initializer-id* names the constructor's class, a non-static data member of the constructor's class, or a direct or virtual base of that class, the *mem-initializer* is ill-formed.

1

A *mem-initializer-list* can initialize a base class using any *class-or-decltype* that denotes that base class type. [*Example:*

```
struct A { A(); };
  typedef A global_A;
  struct B { };
  struct C: public A, public B { C(); };
  C::C(): global_A() { }        // mem-initializer for base A
```

— *end example*]

1 If a *mem-initializer-id* is ambiguous because it designates both a direct non-virtual base class and an inherited virtual base class, the *mem-initializer* is ill-formed. [*Example:*

```
struct A { A(); };
struct B: public virtual A { };
struct C: public A, public B { C(); };
C::C(): A() { }                 // ill-formed: which A?
```

— *end example*]

2

A *ctor-initializer* may initialize a variant member of the constructor's class. If a *ctor-initializer* specifies more than one *mem-initializer* for the same member or for the same base class, the *ctor-initializer* is ill-formed.

1

A *mem-initializer-list* can delegate to another constructor of the constructor's class using any *class-or-decltype* that denotes the constructor's class itself. If a *mem-initializer-id* designates the constructor's class, it shall be the only *mem-initializer*; the constructor is a *delegating constructor*, and the constructor selected by the *mem-initializer* is the *target constructor*. The *principal constructor* is the first constructor invoked in the construction of an object (that is, not a target constructor for that object's construction). The target constructor is selected by overload resolution. Once the target constructor returns, the body of the delegating constructor is executed. If a constructor delegates to itself directly or indirectly, the program is ill-formed; no diagnostic is required. [*Example:*

```
struct C {
  C( int ) { }                  // #1: non-delegating constructor
  C(): C(42) { }                // #2: delegates to #1
  C( char c ) : C(42.0) { }     // #3: ill-formed due to recursion with #4
  C( double d ) : C('a') { }    // #4: ill-formed due to recursion with #3
};
```

— *end example*]

1

The *expression-list* or *braced-init-list* in a *mem-initializer* is used to initialize the designated subobject (or, in the case of a delegating constructor, the complete class object) according to the initialization rules of 8.821 for direct-initialization.

[*Example:*

```
struct B1 { B1(int); /* ... */ };
struct B2 { B2(int); /* ... */ };
struct D : B1, B2 {
  D(int);
  B1 b;
  const int c;
};

D::D(int a) : B2(a+1), B1(a+2), c(a+3), b(a+4)
```

```
  { /* ... */ }
D d(10);
```

— *end example*] The initialization performed by each *mem-initializer* constitutes a full-expression. Any expression in a *mem-initializer* is evaluated as part of the full-expression that performs the initialization. A *mem-initializer* where the *mem-initializer-id* denotes a virtual base class is ignored during execution of a constructor of any class that is not the most derived class.

1

In a non-delegating constructor, if a given potentially constructed subobject is not designated by a *mem-initializer-id* (including the case where there is no *mem-initializer-list* because the constructor has no *ctor-initializer*), then

— if the entity is a non-static data member that has a *brace-or-equal-initializer* and either
  — the constructor's class is a union (9.815), and no other variant member of that union is designated by a *mem-initializer-id* or
  — the constructor's class is not a union, and, if the entity is a member of an anonymous union, no other member of that union is designated by a *mem-initializer-id*,

  the entity is initialized as specified in 8.821;

— otherwise, if the entity is an anonymous union or a variant member (9.815), no initialization is performed;

— otherwise, the entity is default-initialized (8.821).

[*Note:* An abstract class (10.276) is never a most derived class, thus its constructors never initialize virtual base classes, therefore the corresponding *mem-initializer*s may be omitted. — *end note*] An attempt to initialize more than one non-static data member of a union renders the program ill-formed. [*Note:* After the call to a constructor for class `X` for an object with automatic or dynamic storage duration has completed, if the constructor was not invoked as part of value-initialization and a member of `X` is neither initialized nor given a value during execution of the *compound-statement* of the body of the constructor, the member has an indeterminate value. — *end note*] [*Example:*

```
struct A {
  A();
};

struct B {
  B(int);
};

struct C {
  C() { }                 // initializes members as follows:
  A a;                      // OK: calls A::A()
  const B b;                // error: B has no default constructor
  int i;                    // OK: i has indeterminate value
  int j = 5;                // OK: j has the value 5
};
```

— *end example*]

1

If a given non-static data member has both a *brace-or-equal-initializer* and a *mem-initializer*, the initialization specified by the *mem-initializer* is performed, and the non-static data member's *brace-or-equal-initializer* is ignored. [*Example:* Given

```
struct A {
  int i = /* some integer expression with side effects */ ;
  A(int arg) : i(arg) { }
  // ...
};
```

the `A(int)` constructor will simply initialize `i` to the value of `arg`, and the side effects in `i`'s *brace-or-equal-initializer* will not take place. — *end example*]

1

In a non-delegating constructor, the destructor for each potentially constructed subobject of class type is potentially invoked (12.807). [*Note:* This provision ensures that destructors can be called for fully-constructed sub-objects in case an exception is thrown (15.89). — *end note*]

1

In a non-delegating constructor, initialization proceeds in the following order:

— First, and only for the constructor of the most derived class (1.319), virtual base classes are initialized in the order they appear on a depth-first left-to-right traversal of the directed acyclic graph of base classes, where "left-to-right" is the order of appearance of the base classes in the derived class *base-specifier-list*.

— Then, direct base classes are initialized in declaration order as they appear in the *base-specifier-list* (regardless of the order of the *mem-initializers*).

— Then, non-static data members are initialized in the order they were declared in the class definition (again regardless of the order of the *mem-initializers*).

— Finally, the *compound-statement* of the constructor body is executed.

[*Note:* The declaration order is mandated to ensure that base and member subobjects are destroyed in the reverse order of initialization. — *end note*]

1 [*Example:*

```
struct V {
  V();
  V(int);
};

struct A : virtual V {
  A();
  A(int);
};

struct B : virtual V {
  B();
  B(int);
};

struct C : A, B, virtual V {
  C();
  C(int);
};

A::A(int i) : V(i) { /* ... */ }
```

```
B::B(int i) { /* ... */ }
C::C(int i) { /* ... */ }

V v(1);             // use V(int)
A a(2);             // use V(int)
B b(3);             // use V()
C c(4);             // use V()
```

— *end example*]

2

Names in the *expression-list* or *braced-init-list* of a *mem-initializer* are evaluated in the scope of the constructor for which the *mem-initializer* is specified. [*Example:*

```
class X {
  int a;
  int b;
  int i;
  int j;
public:
  const int& r;
  X(int i): r(a), b(i), i(i), j(this->i) { }
};
```

initializes `X::r` to refer to `X::a`, initializes `X::b` with the value of the constructor parameter `i`, initializes `X::i` with the value of the constructor parameter `i`, and initializes `X::j` with the value of `X::i`; this takes place each time an object of class `X` is created. — *end example*] [*Note:* Because the *mem-initializer* are evaluated in the scope of the constructor, the `this` pointer can be used in the *expression-list* of a *mem-initializer* to refer to the object being initialized. — *end note*]

1

Member functions (including virtual member functions, 10.113) can be called for an object under construction. Similarly, an object under construction can be the operand of the `typeid` operator (5.1393.1) or of a `dynamic_cast` (5.1295.1). However, if these operations are performed in a *ctor-initializer* (or in a function called directly or indirectly from a *ctor-initializer*) before all the *mem-initializer*s for base classes have completed, the result of the operation is undefined. [*Example:*

```
class A {
public:
  A(int);
};

class B : public A {
  int j;
public:
  int f();
  B() : A(f()),       // undefined: calls member function
                      // but base A not yet initialized
  j(f()) { }          // well-defined: bases are all initialized
};

class C {
public:
  C(int);
};
```

```
class D : public B, C {
  int i;
public:
  D() : C(f()),       // undefined: calls member function
                      // but base C not yet initialized
  i(f()) { }          // well-defined: bases are all initialized
};
```

— *end example*]

1 [*Note:* 12.1483 describes the result of virtual function calls, `typeid` and `dynamic_cast`s during construction for the well-defined cases; that is, describes the *polymorphic behavior* of an object under construction. — *end note*]

2 A *mem-initializer* followed by an ellipsis is a pack expansion (14.703.1) that initializes the base classes specified by a pack expansion in the *base-specifier-list* for the class. [*Example:*

```
template<class... Mixins>
class X : public Mixins... {
public:
  X(const Mixins&... mixins) : Mixins(mixins)... { }
};
```

— *end example*]

12.1483 Construction and destruction [class.cdtor]

1

For an object with a non-trivial constructor, referring to any non-static member or base class of the object before the constructor begins execution results in undefined behavior. For an object with a non-trivial destructor, referring to any non-static member or base class of the object after the destructor finishes execution results in undefined behavior. [*Example:*

```
struct X { int i; };
struct Y : X { Y(); };                  // non-trivial
struct A { int a; };
struct B : public A { int j; Y y; };    // non-trivial

extern B bobj;
B* pb = &bobj;                          // OK
int* p1 = &bobj.a;                      // undefined, refers to base class member
int* p2 = &bobj.y.i;                    // undefined, refers to member's member

A* pa = &bobj;                          // undefined, upcast to a base class type
B bobj;                                 // definition of bobj

extern X xobj;
int* p3 = &xobj.i;                      //OK, X is a trivial class
X xobj;
```

1 For another example,

```
struct W { int j; };
struct X : public virtual W { };
struct Y {
  int* p;
  X x;
```

```
  Y() : p(&x.j) {    // undefined, x is not yet constructed
    }
};
```

— *end example*]

2

To explicitly or implicitly convert a pointer (a glvalue) referring to an object of class `X` to a pointer (reference) to a direct or indirect base class `B` of `X`, the construction of `X` and the construction of all of its direct or indirect bases that directly or indirectly derive from `B` shall have started and the destruction of these classes shall not have completed, otherwise the conversion results in undefined behavior. To form a pointer to (or access the value of) a direct non-static member of an object `obj`, the construction of `obj` shall have started and its destruction shall not have completed, otherwise the computation of the pointer value (or accessing the member value) results in undefined behavior. [*Example:*

```
struct A { };
struct B : virtual A { };
struct C : B { };
struct D : virtual A { D(A*); };
struct X { X(A*); };

struct E : C, D, X {
  E() : D(this),     // undefined: upcast from E* to A*
                     // might use path E* → D* → A*
                     // but D is not constructed
                     // D((C*)this), // defined:
                     // E* → C* defined because E() has started
                     // and C* → A* defined because
                     // C fully constructed
  X(this) {          // defined: upon construction of X,
                     // C/B/D/A sublattice is fully constructed
  }
};
```

— *end example*]

1

Member functions, including virtual functions (10.113), can be called during construction or destruction (12.1026.1). When a virtual function is called directly or indirectly from a constructor or from a destructor, including during the construction or destruction of the class's non-static data members, and the object to which the call applies is the object (call it `x`) under construction or destruction, the function called is the final overrider in the constructor's or destructor's class and not one overriding it in a more-derived class. If the virtual function call uses an explicit class member access (5.1194.1) and the object expression refers to the complete object of `x` or one of that object's base class subobjects but not `x` or one of its base class subobjects, the behavior is undefined. [*Example:*

```
struct V {
  virtual void f();
  virtual void g();
};

struct A : virtual V {
  virtual void f();
};
```

```
struct B : virtual V {
  virtual void g();
  B(V*, A*);
};

struct D : A, B {
  virtual void f();
  virtual void g();
  D() : B((A*)this, this) { }
};

B::B(V* v, A* a) {
  f();              // calls V::f, not A::f
  g();              // calls B::g, not D::g
  v->g();           // v is base of B, the call is well-defined, calls B::g
  a->f();           // undefined behavior, a's type not a base of B
}
```

— *end example*]

1

The `typeid` operator (5.1393.1) can be used during construction or destruction (12.1026.1). When `typeid` is used in a constructor (including the *mem-initializer* or *brace-or-equal-initializer* for a non-static data member) or in a destructor, or used in a function called (directly or indirectly) from a constructor or destructor, if the operand of `typeid` refers to the object under construction or destruction, `typeid` yields the `std::type_info` object representing the constructor or destructor's class. If the operand of `typeid` refers to the object under construction or destruction and the static type of the operand is neither the constructor or destructor's class nor one of its bases, the result of `typeid` is undefined.

1

`dynamic_cast`s (5.1295.1) can be used during construction or destruction (12.1026.1). When a `dynamic_cast` is used in a constructor (including the *mem-initializer* or *brace-or-equal-initializer* for a non-static data member) or in a destructor, or used in a function called (directly or indirectly) from a constructor or destructor, if the operand of the `dynamic_cast` refers to the object under construction or destruction, this object is considered to be a most derived object that has the type of the constructor or destructor's class. If the operand of the `dynamic_cast` refers to the object under construction or destruction and the static type of the operand is not a pointer to or object of the constructor or destructor's own class or one of its bases, the `dynamic_cast` results in undefined behavior.

[*Example:*

```
struct V {
  virtual void f();
};

struct A : virtual V { };

struct B : virtual V {
  B(V*, A*);
};

struct D : A, B {
  D() : B((A*)this, this) { }
};
```

```
B::B(V* v, A* a) {
  typeid(*this);                // type_info for B
  typeid(*v);                   // well-defined: *v has type V, a base of B
                                // yields type_info for B
  typeid(*a);                   // undefined behavior: type A not a base of B
  dynamic_cast<B*>(v);          // well-defined: v of type V*, V base of B
                                // results in B*
  dynamic_cast<B*>(a);          // undefined behavior,
                                // a has type A*, A not a base of B
}
```

— *end example*]

12.1577 Copying and moving class objects [class.copy]

1

A class object can be copied or moved in two ways: by initialization (12.30, 8.821), including for function argument passing (5.955.1) and for function value return (6.270.2); and by assignment (5.3483). Conceptually, these two operations are implemented by a copy/move constructor (12.30) and copy/move assignment operator (13.1178.1).

1

A non-template constructor for class `X` is a copy constructor if its first parameter is of type `X&`, `const X&`, `volatile X&` or `const volatile X&`, and either there are no other parameters or else all other parameters have default arguments (8.545.1). [*Example:* `X::X(const X&)` and `X::X(X&,int=1)` are copy constructors.

```
struct X {
  X(int);
  X(const X&, int = 1);
};
X a(1);             // calls X(int);
X b(a, 0);          // calls X(const X&, int);
X c = b;            // calls X(const X&, int);
```

— *end example*]

1

A non-template constructor for class `X` is a move constructor if its first parameter is of type `X&&`, `const X&&`, `volatile X&&`, or `const volatile X&&`, and either there are no other parameters or else all other parameters have default arguments (8.545.1). [*Example:* `Y::Y(Y&&)` is a move constructor.

```
struct Y {
  Y(const Y&);
  Y(Y&&);
};
extern Y f(int);
Y d(f(1));          // calls Y(Y&&)
Y e = d;            // calls Y(const Y&)
```

— *end example*]

1 [*Note:* All forms of copy/move constructor may be declared for a class. [*Example:*

```
struct X {
  X(const X&);
  X(X&);            // OK
  X(X&&);
```

```
  X(const X&&);       // OK, but possibly not sensible
};
```

— *end example*] — *end note*]

2 [*Note:* If a class `X` only has a copy constructor with a parameter of type `X&`, an initializer of type `const X` or `volatile X` cannot initialize an object of type (possibly cv-qualified) `X`. [*Example:*

```
struct X {
  X();                // default constructor
  X(X&);              // copy constructor with a nonconst parameter
};
const X cx;
X x = cx;             // error: X::X(X&) cannot copy cx into x
```

— *end example*] — *end note*]

3

A declaration of a constructor for a class `X` is ill-formed if its first parameter is of type (optionally cv-qualified) `X` and either there are no other parameters or else all other parameters have default arguments. A member function template is never instantiated to produce such a constructor signature. [*Example:*

```
struct S {
  template<typename T> S(T);
  S();
};

S g;

void h() {
  S a(g);             // does not instantiate the member template to produce S::S<S>(S);
                      // uses the implicitly declared copy constructor
}
```

— *end example*]

1

If the class definition does not explicitly declare a copy constructor, one is declared *implicitly*. If the class definition declares a move constructor or move assignment operator, the implicitly declared copy constructor is defined as deleted; otherwise, it is defined as defaulted (8.706). The latter case is deprecated if the class has a user-declared copy assignment operator or a user-declared destructor.

1

The implicitly-declared copy constructor for a class `X` will have the form

```
X::X(const X&)
```

if each potentially constructed subobject of a class type `M` (or array thereof) has a copy constructor whose first parameter is of type `const M&` or `const volatile M&`.[120] Otherwise, the implicitly-declared copy constructor will have the form

```
X::X(X&)
```

1

120) This implies that the reference parameter of the implicitly-declared copy constructor cannot bind to a `volatile` lvalue; see C.1.9.

If the definition of a class `X` does not explicitly declare a move constructor, one will be implicitly declared as defaulted if and only if

— `X` does not have a user-declared copy constructor,

— `X` does not have a user-declared copy assignment operator,

— `X` does not have a user-declared move assignment operator, and

— `X` does not have a user-declared destructor.

[*Note:* When the move constructor is not implicitly declared or explicitly supplied, expressions that otherwise would have invoked the move constructor may instead invoke a copy constructor. — *end note*]

1

The implicitly-declared move constructor for class `X` will have the form

```
X::X(X&&)
```

1

An implicitly-declared copy/move constructor is an `inline public` member of its class. A defaulted copy/move constructor for a class `X` is defined as deleted (8.793.1) if `X` has:

— a variant member with a non-trivial corresponding constructor and `X` is a union-like class,

— a potentially constructed subobject type `M` (or array thereof) that cannot be copied/moved because overload resolution (13.88), as applied to `M`'s corresponding constructor, results in an ambiguity or a function that is deleted or inaccessible from the defaulted constructor,

— any potentially constructed subobject of a type with a destructor that is deleted or inaccessible from the defaulted constructor, or,

— for the copy constructor, a non-static data member of rvalue reference type.

A defaulted move constructor that is defined as deleted is ignored by overload resolution (13.88, 13.1084). [*Note:* A deleted move constructor would otherwise interfere with initialization from an rvalue which can use the copy constructor instead. — *end note*]

1

A copy/move constructor for class `X` is trivial if it is not user-provided, its parameter-type-list is equivalent to the parameter-type-list of an implicit declaration, and if

— class `X` has no virtual functions (10.113) and no virtual base classes (10.31), and

— class `X` has no non-static data members of volatile-qualified type, and

— the constructor selected to copy/move each direct base class subobject is trivial, and

— for each non-static data member of `X` that is of class type (or array thereof), the constructor selected to copy/move that member is trivial;

otherwise the copy/move constructor is *non-trivial*.

1

A copy/move constructor that is defaulted and not defined as deleted is *implicitly defined* if it is odr-used (3.91) or when it is explicitly defaulted after its first declaration. [*Note:* The copy/move constructor is

implicitly defined even if the implementation elided its odr-use (3.91, 12.306). — *end note*] If the implicitly-defined constructor would satisfy the requirements of a `constexpr` constructor (7.328.1), the implicitly-defined constructor is `constexpr`.

1 Before the defaulted copy/move constructor for a class is implicitly defined, all non-user-provided copy/-move constructors for its potentially constructed subobjects shall have been implicitly defined. [*Note:* An implicitly-declared copy/move constructor has an *exception-specification* (15.228). — *end note*]

2

The implicitly-defined copy/move constructor for a non-union class `X` performs a memberwise copy/move of its bases and members. [*Note: brace-or-equal-initializer*s of non-static data members are ignored. See also the example in 12.1026.1. — *end note*] The order of initialization is the same as the order of initialization of bases and members in a user-defined constructor (see 12.1026.1). Let `x` be either the parameter of the constructor or, for the move constructor, an xvalue referring to the parameter. Each base or non-static data member is copied/moved in the manner appropriate to its type:

— if the member is an array, each element is direct-initialized with the corresponding subobject of `x`;

— if a member `m` has rvalue reference type `T&&`, it is direct-initialized with `static_cast<T&&>(x.m)`;

— otherwise, the base or member is direct-initialized with the corresponding base or member of `x`.

Virtual base class subobjects shall be initialized only once by the implicitly-defined copy/move constructor (see 12.1026.1).

1

The implicitly-defined copy/move constructor for a union `X` copies the object representation (3.2955) of `X`.

1

A user-declared *copy* assignment operator `X::operator=` is a non-static non-template member function of class `X` with exactly one parameter of type `X`, `X&`, `const X&`, `volatile X&` or `const volatile X&`.[121] [*Note:* An overloaded assignment operator must be declared to have only one parameter; see 13.1178.1. — *end note*] [*Note:* More than one form of copy assignment operator may be declared for a class. — *end note*] [*Note:* If a class `X` only has a copy assignment operator with a parameter of type `X&`, an expression of type const `X` cannot be assigned to an object of type `X`. [*Example:*

```
struct X {
  X();
  X& operator=(X&);
};
const X cx;
X x;
void f() {
  x = cx;            // error: X::operator=(X&) cannot assign cx into x
}
```

— *end example*] — *end note*]

1

If the class definition does not explicitly declare a copy assignment operator, one is declared *implicitly*. If the class definition declares a move constructor or move assignment operator, the implicitly declared copy assignment operator is defined as deleted; otherwise, it is defined as defaulted (8.706). The latter case is

121) Because a template assignment operator or an assignment operator taking an rvalue reference parameter is never a copy assignment operator, the presence of such an assignment operator does not suppress the implicit declaration of a copy assignment operator. Such assignment operators participate in overload resolution with other assignment operators, including copy assignment operators, and, if selected, will be used to assign an object.

deprecated if the class has a user-declared copy constructor or a user-declared destructor. The implicitly-declared copy assignment operator for a class `X` will have the form

```
X& X::operator=(const X&)
```

if

— each direct base class `B` of `X` has a copy assignment operator whose parameter is of type `const B&`, `const volatile B&` or `B`, and

— for all the non-static data members of `X` that are of a class type `M` (or array thereof), each such class type has a copy assignment operator whose parameter is of type `const M&`, `const volatile M&` or `M`.[122]

Otherwise, the implicitly-declared copy assignment operator will have the form

```
X& X::operator=(X&)
```

1

A user-declared move assignment operator `X::operator=` is a non-static non-template member function of class `X` with exactly one parameter of type `X&&`, `const X&&`, `volatile X&&`, or `const volatile X&&`. [*Note:* An overloaded assignment operator must be declared to have only one parameter; see 13.1178.1. — *end note*] [*Note:* More than one form of move assignment operator may be declared for a class. — *end note*]

1

If the definition of a class `X` does not explicitly declare a move assignment operator, one will be implicitly declared as defaulted if and only if

— `X` does not have a user-declared copy constructor,

— `X` does not have a user-declared move constructor,

— `X` does not have a user-declared copy assignment operator, and

— `X` does not have a user-declared destructor.

[*Example:* The class definition

```
struct S {
  int a;
  S& operator=(const S&) = default;
};
```

will not have a default move assignment operator implicitly declared because the copy assignment operator has been user-declared. The move assignment operator may be explicitly defaulted.

```
struct S {
  int a;
  S& operator=(const S&) = default;
  S& operator=(S&&) = default;
};
```

— *end example*]

1 The implicitly-declared move assignment operator for a class `X` will have the form

```
X& X::operator=(X&&);
```

122) This implies that the reference parameter of the implicitly-declared copy assignment operator cannot bind to a `volatile` lvalue; see C.1.9.

2 The implicitly-declared copy/move assignment operator for class `X` has the return type `X&`; it returns the object for which the assignment operator is invoked, that is, the object assigned to. An implicitly-declared copy/move assignment operator is an `inline public` member of its class.

3

A defaulted copy/move assignment operator for class `X` is defined as deleted if `X` has:

— a variant member with a non-trivial corresponding assignment operator and `X` is a union-like class, or

— a non-static data member of `const` non-class type (or array thereof), or

— a non-static data member of reference type, or

— a potentially constructed subobject of class type `M` (or array thereof) that cannot be copied/moved because overload resolution (13.88), as applied to `M`'s corresponding assignment operator, results in an ambiguity or a function that is deleted or inaccessible from the defaulted assignment operator.

A defaulted move assignment operator that is defined as deleted is ignored by overload resolution (13.88, 13.1084).

1

Because a copy/move assignment operator is implicitly declared for a class if not declared by the user, a base class copy/move assignment operator is always hidden by the corresponding assignment operator of a derived class (13.1178.1). A *using-declaration* (7.1311.1) that brings in from a base class an assignment operator with a parameter type that could be that of a copy/move assignment operator for the derived class is not considered an explicit declaration of such an operator and does not suppress the implicit declaration of the derived class operator; the operator introduced by the *using-declaration* is hidden by the implicitly-declared operator in the derived class.

1

A copy/move assignment operator for class `X` is trivial if it is not user-provided, its parameter-type-list is equivalent to the parameter-type-list of an implicit declaration, and if

— class `X` has no virtual functions (10.113) and no virtual base classes (10.31), and

— class `X` has no non-static data members of volatile-qualified type, and

— the assignment operator selected to copy/move each direct base class subobject is trivial, and

— for each non-static data member of `X` that is of class type (or array thereof), the assignment operator selected to copy/move that member is trivial;

otherwise the copy/move assignment operator is *non-trivial*.

1 A copy/move assignment operator for a class `X` that is defaulted and not defined as deleted is *implicitly defined* when it is odr-used (3.91) (e.g., when it is selected by overload resolution to assign to an object of its class type) or when it is explicitly defaulted after its first declaration. The implicitly-defined copy/move assignment operator is `constexpr` if

(1.1) — `X` is a literal type, and

(1.2) — the assignment operator selected to copy/move each direct base class subobject is a `constexpr` function, and

(1.3) — for each non-static data member of `X` that is of class type (or array thereof), the assignment operator selected to copy/move that member is a `constexpr` function.

2 Before the defaulted copy/move assignment operator for a class is implicitly defined, all non-user-provided copy/move assignment operators for its direct base classes and its non-static data members shall have been implicitly defined. [*Note:* An implicitly-declared copy/move assignment operator has an *exception-specification* (15.228). — *end note*]

3

The implicitly-defined copy/move assignment operator for a non-union class `X` performs memberwise copy-/move assignment of its subobjects. The direct base classes of `X` are assigned first, in the order of their declaration in the *base-specifier-list*, and then the immediate non-static data members of `X` are assigned, in the order in which they were declared in the class definition. Let `x` be either the parameter of the function or, for the move operator, an xvalue referring to the parameter. Each subobject is assigned in the manner appropriate to its type:

— if the subobject is of class type, as if by a call to `operator=` with the subobject as the object expression and the corresponding subobject of `x` as a single function argument (as if by explicit qualification; that is, ignoring any possible virtual overriding functions in more derived classes);

— if the subobject is an array, each element is assigned, in the manner appropriate to the element type;

— if the subobject is of scalar type, the built-in assignment operator is used.

It is unspecified whether subobjects representing virtual base classes are assigned more than once by the implicitly-defined copy assignment operator. [*Example:*

```
struct V { };
struct A : virtual V { };
struct B : virtual V { };
struct C : B, A { };
```

It is unspecified whether the virtual base class subobject `V` is assigned twice by the implicitly-defined copy assignment operator for `C`. — *end example*] [*Note:* This does not apply to move assignment, as a defaulted move assignment operator is deleted if the class has virtual bases. — *end note*]

1

The implicitly-defined copy assignment operator for a union `X` copies the object representation (3.2955) of `X`.

1

A program is ill-formed if the copy/move constructor or the copy/move assignment operator for an object is implicitly odr-used and the special member function is not accessible (Clause 11). [*Note:* Copying/moving one object into another using the copy/move constructor or the copy/move assignment operator does not change the layout or size of either object. — *end note*]

1

When certain criteria are met, an implementation is allowed to omit the copy/move construction of a class object, even if the constructor selected for the copy/move operation and/or the destructor for the object have side effects. In such cases, the implementation treats the source and target of the omitted copy/move operation as simply two different ways of referring to the same object, and the destruction of that object occurs at the later of the times when the two objects would have been destroyed without the optimization.[123] This elision of copy/move operations, called *copy elision*, is permitted in the following circumstances (which may be combined to eliminate multiple copies):

123) Because only one object is destroyed instead of two, and one copy/move constructor is not executed, there is still one object destroyed for each one constructed.

— in a `return` statement in a function with a class return type, when the expression is the name of a non-volatile automatic object (other than a function or catch-clause parameter) with the same cv-unqualified type as the function return type, the copy/move operation can be omitted by constructing the automatic object directly into the function's return value

— in a *throw-expression*, when the operand is the name of a non-volatile automatic object (other than a function or catch-clause parameter) whose scope does not extend beyond the end of the innermost enclosing *try-block* (if there is one), the copy/move operation from the operand to the exception object (15.7) can be omitted by constructing the automatic object directly into the exception object

— when a temporary class object that has not been bound to a reference (12.306) would be copied/moved to a class object with the same cv-unqualified type, the copy/move operation can be omitted by constructing the temporary object directly into the target of the omitted copy/move

— when the *exception-declaration* of an exception handler (Clause 15) declares an object of the same type (except for cv-qualification) as the exception object (15.7), the copy operation can be omitted by treating the *exception-declaration* as an alias for the exception object if the meaning of the program will be unchanged except for the execution of constructors and destructors for the object declared by the *exception-declaration*. [*Note:* There cannot be a move from the exception object because it is always an lvalue. — *end note*]

[*Example:*

```
class Thing {
public:
  Thing();
  ~Thing();
  Thing(const Thing&);
};

Thing f() {
  Thing t;
  return t;
}

Thing t2 = f();
```

Here the criteria for elision can be combined to eliminate two calls to the copy constructor of class `Thing`: the copying of the local automatic object `t` into the temporary object for the return value of function `f()` and the copying of that temporary object into object `t2`. Effectively, the construction of the local object `t` can be viewed as directly initializing the global object `t2`, and that object's destruction will occur at program exit. Adding a move constructor to `Thing` has the same effect, but it is the move construction from the temporary object to `t2` that is elided. — *end example*]

1

When the criteria for elision of a copy/move operation are met, but not for an *exception-declaration*, and the object to be copied is designated by an lvalue, or when the *expression* in a `return` statement is a (possibly parenthesized) *id-expression* that names an object with automatic storage duration declared in the body or *parameter-declaration-clause* of the innermost enclosing function or *lambda-expression*, overload resolution to select the constructor for the copy is first performed as if the object were designated by an rvalue. If the first overload resolution fails or was not performed, or if the type of the first parameter of the selected constructor is not an rvalue reference to the object's type (possibly cv-qualified), overload resolution is performed again, considering the object as an lvalue. [*Note:* This two-stage overload resolution must be performed regardless of whether copy elision will occur. It determines the constructor to be called if elision is not performed, and the selected constructor must be accessible even if the call is elided. — *end note*]

[*Example:*

```
class Thing {
public:
  Thing();
  ~Thing();
  Thing(Thing&&);
private:
  Thing(const Thing&);
};

Thing f(bool b) {
  Thing t;
  if (b)
    throw t;                    // OK: Thing(Thing&&) used (or elided) to throw t
  return t;                     // OK: Thing(Thing&&) used (or elided) to return t
}

Thing t2 = f(false);            // OK: Thing(Thing&&) used (or elided) to construct t2
```

— *end example*]

12.2400 Inheriting constructors [class.inhctor]

1

A *using-declaration* (7.1311.1) that names a constructor implicitly declares a set of *inheriting constructors*. The *candidate set of inherited constructors* from the class `X` named in the *using-declaration* consists of actual constructors and notional constructors that result from the transformation of defaulted parameters as follows:

— all non-template constructors of `X`, and

— for each non-template constructor of `X` that has at least one parameter with a default argument, the set of constructors that results from omitting any ellipsis parameter specification and successively omitting parameters with a default argument from the end of the parameter-type-list, and

— all constructor templates of `X`, and

— for each constructor template of `X` that has at least one parameter with a default argument, the set of constructor templates that results from omitting any ellipsis parameter specification and successively omitting parameters with a default argument from the end of the parameter-type-list.

1 The *constructor characteristics* of a constructor or constructor template are

(1.1) — the template parameter list (14.97), if any,

(1.2) — the *parameter-type-list* (8.360.1),

(1.3) — absence or presence of `explicit` (12.708.1), and

(1.4) — absence or presence of `constexpr` (7.328.1).

2

For each non-template constructor in the candidate set of inherited constructors other than a constructor having no parameters or a copy/move constructor having a single parameter, a constructor is implicitly declared with the same constructor characteristics unless there is a user-declared constructor with the same signature in the complete class where the *using-declaration* appears or the constructor would be a default,

copy, or move constructor for that class. Similarly, for each constructor template in the candidate set of inherited constructors, a constructor template is implicitly declared with the same constructor characteristics unless there is an equivalent user-declared constructor template (14.975.0.1) in the complete class where the *using-declaration* appears. [*Note:* Default arguments are not inherited. An *exception-specification* is implied as specified in 15.228. — *end note*]

1

A constructor so declared has the same access as the corresponding constructor in `X`. It is deleted if the corresponding constructor in `X` is deleted (8.706). An inheriting constructor shall not be explicitly instantiated (14.1841.1) or explicitly specialized (14.1921.1).

1

[*Note:* Default and copy/move constructors may be implicitly declared as specified in 12.30 and 12.1577. — *end note*]

1 [*Example:*

```
struct B1 {
  B1(int);
};

struct B2 {
  B2(int = 13, int = 42);
};

struct D1 : B1 {
  using B1::B1;
};

struct D2 : B2 {
  using B2::B2;
};
```

The candidate set of inherited constructors in `D1` for `B1` is

— `B1(const B1&)`

— `B1(B1&&)`

— `B1(int)`

The set of constructors present in `D1` is

— `D1()`, implicitly-declared default constructor, ill-formed if odr-used

— `D1(const D1&)`, implicitly-declared copy constructor, not inherited

— `D1(D1&&)`, implicitly-declared move constructor, not inherited

— `D1(int)`, implicitly-declared inheriting constructor

The candidate set of inherited constructors in `D2` for `B2` is

— `B2(const B2&)`

— `B2(B2&&)`

— `B2(int = 13, int = 42)`

— `B2(int = 13)`

— `B2()`

The set of constructors present in `D2` is

— `D2()`, implicitly-declared default constructor, not inherited

— `D2(const D2&)`, implicitly-declared copy constructor, not inherited

— `D2(D2&&)`, implicitly-declared move constructor, not inherited

— `D2(int, int)`, implicitly-declared inheriting constructor

— `D2(int)`, implicitly-declared inheriting constructor

— *end example*]

1

[*Note:* If two *using-declaration*s declare inheriting constructors with the same signatures, the program is ill-formed (9.194, 13.12), because an implicitly-declared constructor introduced by the first *using-declaration* is not a user-declared constructor and thus does not preclude another declaration of a constructor with the same signature by a subsequent *using-declaration*. [*Example:*

```
struct B1 {
  B1(int);
};

struct B2 {
  B2(int);
};

struct D1 : B1, B2 {
  using B1::B1;
  using B2::B2;
};                    // ill-formed: attempts to declare D1(int) twice

struct D2 : B1, B2 {
  using B1::B1;
  using B2::B2;
  D2(int);            // OK: user declaration supersedes both implicit declarations
};
```

— *end example*] — *end note*]

1

An inheriting constructor for a class is implicitly defined when it is odr-used (3.91) to create an object of its class type (1.319). An implicitly-defined inheriting constructor performs the set of initializations of the class that would be performed by a user-written `inline` constructor for that class with a *mem-initializer-list* whose only *mem-initializer* has a *mem-initializer-id* that names the base class denoted in the *nested-name-specifier* of the *using-declaration* and an *expression-list* as specified below, and where the *compound-statement* in its function body is empty (12.1026.1). If that user-written constructor would be ill-formed, the program is ill-formed. Each *expression* in the *expression-list* is of the form `static_cast<T&&>(p)`, where `p` is the name of the corresponding constructor parameter and `T` is the declared type of `p`.

1

[*Example:*

```
struct B1 {
  B1(int) { }
};

struct B2 {
  B2(double) { }
};

struct D1 : B1 {
  using B1::B1;      // implicitly declares D1(int)
  int x;
};

void test() {
  D1 d(6);           // OK: d.x is not initialized
  D1 e;              // error: D1 has no default constructor
}

struct D2 : B2 {
  using B2::B2;      // OK: implicitly declares D2(double)
  B1 b;
};

D2 f(1.0);           // error: B1 has no default constructor

template< class T >
struct D : T {
  using T::T;        // declares all constructors from class T
  ~D() { std::clog << "Destroying wrapper" << std::endl; }
};
```

Class template `D` wraps any class and forwards all of its constructors, while writing a message to the standard log whenever an object of class `D` is destroyed. — *end example*]

13 Overloading [over]

1

When two or more different declarations are specified for a single name in the same scope, that name is said to be *overloaded*. By extension, two declarations in the same scope that declare the same name but with different types are called *overloaded declarations*. Only function and function template declarations can be overloaded; variable and type declarations cannot be overloaded.

1

When an overloaded function name is used in a call, which overloaded function declaration is being referenced is determined by comparing the types of the arguments at the point of use with the types of the parameters in the overloaded declarations that are visible at the point of use. This function selection process is called *overload resolution* and is defined in 13.88. [*Example:*

```
double abs(double);
int abs(int);

abs(1);             // calls abs(int);
abs(1.0);           // calls abs(double);
```

— *end example*]

13.12 Overloadable declarations [over.load]

1

Not all function declarations can be overloaded. Those that cannot be overloaded are specified here. A program is ill-formed if it contains two such non-overloadable declarations in the same scope. [*Note:* This restriction applies to explicit declarations in a scope, and between such declarations and declarations made through a *using-declaration* (7.1311.1). It does not apply to sets of functions fabricated as a result of name lookup (e.g., because of *using-directives*) or overload resolution (e.g., for operator functions). — *end note*]

1

Certain function declarations cannot be overloaded:

— Function declarations that differ only in the return type cannot be overloaded.

— Member function declarations with the same name and the same *parameter-type-list* cannot be overloaded if any of them is a `static` member function declaration (9.559). Likewise, member function template declarations with the same name, the same *parameter-type-list*, and the same template parameter lists cannot be overloaded if any of them is a `static` member function template declaration. The types of the implicit object parameters constructed for the member functions for the purpose of overload resolution (13.133.1) are not considered when comparing parameter-type-lists for enforcement of this rule. In contrast, if there is no `static` member function declaration among a set of member function declarations with the same name and the same parameter-type-list, then these member function declarations can be overloaded if they differ in the type of their implicit object parameter. [*Example:* the following illustrates this distinction:

```
class X {
  static void f();
  void f();                    // ill-formed
  void f() const;              // ill-formed
```

```
  void f() const volatile;      // ill-formed
  void g();
  void g() const;               // OK: no static g
  void g() const volatile;      // OK: no static g
};
```

— *end example*]

— Member function declarations with the same name and the same *parameter-type-list* as well as member function template declarations with the same name, the same *parameter-type-list*, and the same template parameter lists cannot be overloaded if any of them, but not all, have a *ref-qualifier* (8.360.1). [*Example:*

```
class Y {
  void h() &;
  void h() const &;             // OK
  void h() &&;                  // OK, all declarations have a ref-qualifier
  void i() &;
  void i() const;               // ill-formed, prior declaration of i
                                // has a ref-qualifier
};
```

— *end example*]

1

[*Note:* As specified in 8.360.1, function declarations that have equivalent parameter declarations declare the same function and therefore cannot be overloaded:

— Parameter declarations that differ only in the use of equivalent typedef "types" are equivalent. A `typedef` is not a separate type, but only a synonym for another type (7.235.1). [*Example:*

```
typedef int Int;

void f(int i);
void f(Int i);                  // OK: redeclaration of f(int)
void f(int i) { /* ...  */ }
void f(Int i) { /* ...  */ }    // error: redefinition of f(int)
```

— *end example*]

Enumerations, on the other hand, are distinct types and can be used to distinguish overloaded function declarations. [*Example:*

```
enum E { a };

void f(int i) { /* ...  */ }
void f(E i)   { /* ...  */ }
```

— *end example*]

— Parameter declarations that differ only in a pointer `*` versus an array `[]` are equivalent. That is, the array declaration is adjusted to become a pointer declaration (8.360.1). Only the second and subsequent array dimensions are significant in parameter types (8.251.1). [*Example:*

```
int f(char*);
int f(char[]);                  // same as f(char*);
int f(char[7]);                 // same as f(char*);
int f(char[9]);                 // same as f(char*);
```

```
int g(char(*)[10]);
int g(char[5][10]);              // same as g(char(*)[10]);
int g(char[7][10]);              // same as g(char(*)[10]);
int g(char(*)[20]);              // different from g(char(*)[10]);
```

— *end example*]

— Parameter declarations that differ only in that one is a function type and the other is a pointer to the same function type are equivalent. That is, the function type is adjusted to become a pointer to function type (8.360.1). [*Example:*

```
void h(int());
void h(int (*)());               // redeclaration of h(int())
void h(int x()) { }              // definition of h(int())
void h(int (*x)()) { }           // ill-formed: redefinition of h(int())
```

— *end example*]

— Parameter declarations that differ only in the presence or absence of `const` and/or `volatile` are equivalent. That is, the `const` and `volatile` type-specifiers for each parameter type are ignored when determining which function is being declared, defined, or called. [*Example:*

```
typedef const int cInt;

int f (int);
int f (const int);               // redeclaration of f(int)
int f (int) { /* ...  */ }       // definition of f(int)
int f (cInt) { /* ...  */ }      // error: redefinition of f(int)
```

— *end example*]

Only the `const` and `volatile` type-specifiers at the outermost level of the parameter type specification are ignored in this fashion; `const` and `volatile` type-specifiers buried within a parameter type specification are significant and can be used to distinguish overloaded function declarations.[124] In particular, for any type `T`, "pointer to `T`," "pointer to `const T`," and "pointer to `volatile T`" are considered distinct parameter types, as are "reference to `T`," "reference to `const T`," and "reference to `volatile T`."

— Two parameter declarations that differ only in their default arguments are equivalent. [*Example:* consider the following:

```
void f (int i, int j);
void f (int i, int j = 99);      // OK: redeclaration of f(int, int)
void f (int i = 88, int j);      // OK: redeclaration of f(int, int)
void f ();                       // OK: overloaded declaration of f

void prog () {
    f (1, 2);                    // OK: call f(int, int)
    f (1);                       // OK: call f(int, int)
    f ();                        // Error: f(int, int) or f()?
}
```

— *end example*] — *end note*]

124) When a parameter type includes a function type, such as in the case of a parameter type that is a pointer to function, the `const` and `volatile` type-specifiers at the outermost level of the parameter type specifications for the inner function type are also ignored.

13.85 Declaration matching [over.dcl]

1

Two function declarations of the same name refer to the same function if they are in the same scope and have equivalent parameter declarations (13.12). A function member of a derived class is *not* in the same scope as a function member of the same name in a base class. [*Example:*

```
struct B {
  int f(int);
};

struct D : B {
  int f(const char*);
};
```

Here `D::f(const char*)` hides `B::f(int)` rather than overloading it.

```
void h(D* pd) {
  pd->f(1);                    // error:
                               // D::f(const char*) hides B::f(int)
  pd->B::f(1);                 // OK
  pd->f("Ben");                // OK, calls D::f
}
```

— *end example*]

1 A locally declared function is not in the same scope as a function in a containing scope. [*Example:*

```
void f(const char*);
void g() {
  extern void f(int);
  f("asdf");                   // error: f(int) hides f(const char*)
                               // so there is no f(const char*) in this scope
}

void caller () {
  extern void callee(int, int);
  {
    extern void callee(int);   // hides callee(int, int)
    callee(88, 99);            // error: only callee(int) in scope
  }
}
```

— *end example*]

2 Different versions of an overloaded member function can be given different access rules. [*Example:*

```
class buffer {
private:
    char* p;
    int size;
protected:
    buffer(int s, char* store) { size = s; p = store; }
public:
    buffer(int s) { p = new char[size = s]; }
};
```

— *end example*]

13.88 Overload resolution [over.match]

1

Overload resolution is a mechanism for selecting the best function to call given a list of expressions that are to be the arguments of the call and a set of *candidate functions* that can be called based on the context of the call. The selection criteria for the best function are the number of arguments, how well the arguments match the parameter-type-list of the candidate function, how well (for non-static member functions) the object matches the implicit object parameter, and certain other properties of the candidate function. [*Note:* The function selected by overload resolution is not guaranteed to be appropriate for the context. Other restrictions, such as the accessibility of the function, can make its use in the calling context ill-formed. — *end note*]

1

Overload resolution selects the function to call in seven distinct contexts within the language:

— invocation of a function named in the function call syntax (13.230.0.1.1);

— invocation of a function call operator, a pointer-to-function conversion function, a reference-to-pointer-to-function conversion function, or a reference-to-function conversion function on a class object named in the function call syntax (13.250.0.0.1);

— invocation of the operator referenced in an expression (13.264.0.1);

— invocation of a constructor for direct-initialization (8.821) of a class object (13.354.0.1);

— invocation of a user-defined conversion for copy-initialization (8.821) of a class object (13.368.0.1);

— invocation of a conversion function for initialization of an object of a nonclass type from an expression of class type (13.396.0.1); and

— invocation of a conversion function for conversion to a glvalue or class prvalue to which a reference (8.2156.1) will be directly bound (13.413.0.1).

Each of these contexts defines the set of candidate functions and the list of arguments in its own unique way. But, once the candidate functions and argument lists have been identified, the selection of the best function is the same in all cases:

— First, a subset of the candidate functions (those that have the proper number of arguments and meet certain other conditions) is selected to form a set of viable functions (13.530.1).

— Then the best viable function is selected based on the implicit conversion sequences (13.779.0.1) needed to match each argument to the corresponding parameter of each viable function.

1

If a best viable function exists and is unique, overload resolution succeeds and produces it as the result. Otherwise overload resolution fails and the invocation is ill-formed. When overload resolution succeeds, and the best viable function is not accessible (Clause 11) in the context in which it is used, the program is ill-formed.

13.133.1 Candidate functions and argument lists [over.match.funcs]

1

The subclauses of 13.133.1 describe the set of candidate functions and the argument list submitted to overload resolution in each of the seven contexts in which overload resolution is used. The source transformations and constructions defined in these subclauses are only for the purpose of describing the overload resolution process. An implementation is not required to use such transformations and constructions.

1

The set of candidate functions can contain both member and non-member functions to be resolved against the same argument list. So that argument and parameter lists are comparable within this heterogeneous set, a member function is considered to have an extra parameter, called the *implicit object parameter*, which represents the object for which the member function has been called. For the purposes of overload resolution, both static and non-static member functions have an implicit object parameter, but constructors do not.

1

Similarly, when appropriate, the context can construct an argument list that contains an *implied object argument* to denote the object to be operated on. Since arguments and parameters are associated by position within their respective lists, the convention is that the implicit object parameter, if present, is always the first parameter and the implied object argument, if present, is always the first argument.

1

For non-static member functions, the type of the implicit object parameter is

— "lvalue reference to *cv* `X`" for functions declared without a *ref-qualifier* or with the `&` *ref-qualifier*

— "rvalue reference to *cv* `X`" for functions declared with the `&&` *ref-qualifier*

where `X` is the class of which the function is a member and *cv* is the cv-qualification on the member function declaration. [*Example:* for a `const` member function of class `X`, the extra parameter is assumed to have type "reference to `const X`". — *end example*] For conversion functions, the function is considered to be a member of the class of the implied object argument for the purpose of defining the type of the implicit object parameter. For non-conversion functions introduced by a *using-declaration* into a derived class, the function is considered to be a member of the derived class for the purpose of defining the type of the implicit object parameter. For static member functions, the implicit object parameter is considered to match any object (since if the function is selected, the object is discarded). [*Note:* No actual type is established for the implicit object parameter of a static member function, and no attempt will be made to determine a conversion sequence for that parameter (13.562.1). — *end note*]

1

During overload resolution, the implied object argument is indistinguishable from other arguments. The implicit object parameter, however, retains its identity since conversions on the corresponding argument shall obey these additional rules:

— no temporary object can be introduced to hold the argument for the implicit object parameter; and

— no user-defined conversions can be applied to achieve a type match with it.

For non-static member functions declared without a *ref-qualifier*, an additional rule applies:

— even if the implicit object parameter is not `const`-qualified, an rvalue can be bound to the parameter as long as in all other respects the argument can be converted to the type of the implicit object parameter. [*Note:* The fact that such an argument is an rvalue does not affect the ranking of implicit conversion sequences (13.946.0.1). — *end note*]

1 Because other than in list-initialization only one user-defined conversion is allowed in an implicit conversion sequence, special rules apply when selecting the best user-defined conversion (13.562.1, 13.779.0.1). [*Example:*

```
class T {
public:
  T();
};
```

```
class C : T {
public:
  C(int);
};
T a = 1;              // ill-formed: T(C(1)) not tried
```

— *end example*]

2

In each case where a candidate is a function template, candidate function template specializations are generated using template argument deduction (14.2662.1, 14.2114.1). Those candidates are then handled as candidate functions in the usual way.[125] A given name can refer to one or more function templates and also to a set of overloaded non-template functions. In such a case, the candidate functions generated from each function template are combined with the set of non-template candidate functions.

1 A defaulted move constructor or assignment operator (12.1577) that is defined as deleted is excluded from the set of candidate functions in all contexts.

13.230.0.1 Function call syntax [over.match.call]

1 In a function call (5.955.1)

postfix-expression `(` *expression-list*$_{opt}$`)`

if the *postfix-expression* denotes a set of overloaded functions and/or function templates, overload resolution is applied as specified in 13.230.0.1.1. If the *postfix-expression* denotes an object of class type, overload resolution is applied as specified in 13.250.0.0.1.

2 If the *postfix-expression* denotes the address of a set of overloaded functions and/or function templates, overload resolution is applied using that set as described above. If the function selected by overload resolution is a non-static member function, the program is ill-formed. [*Note:* The resolution of the address of an overload set in other contexts is described in 13.1084. — *end note*]

13.230.0.1.1 Call to named function [over.call.func]

1 Of interest in 13.230.0.1.1 are only those function calls in which the *postfix-expression* ultimately contains a name that denotes one or more functions that might be called. Such a *postfix-expression*, perhaps nested arbitrarily deep in parentheses, has one of the following forms:

postfix-expression:
  postfix-expression `.` *id-expression*
  postfix-expression `->` *id-expression*
  primary-expression

These represent two syntactic subcategories of function calls: qualified function calls and unqualified function calls.

2

In qualified function calls, the name to be resolved is an *id-expression* and is preceded by an `->` or `.` operator. Since the construct `A->B` is generally equivalent to `(*A).B`, the rest of Clause 13 assumes, without loss of generality, that all member function calls have been normalized to the form that uses an object and the `.` operator. Furthermore, Clause 13 assumes that the *postfix-expression* that is the left operand of the `.` operator has type "*cv* `T`" where `T` denotes a class[126]. Under this assumption, the *id-expression* in the call

125) The process of argument deduction fully determines the parameter types of the function template specializations, i.e., the parameters of function template specializations contain no template parameter types. Therefore, except where specified otherwise, function template specializations and non-template functions (8.360.1) are treated equivalently for the remainder of overload resolution.

126) Note that cv-qualifiers on the type of objects are significant in overload resolution for both glvalue and class prvalue objects.

is looked up as a member function of `T` following the rules for looking up names in classes (10.52). The function declarations found by that lookup constitute the set of candidate functions. The argument list is the *expression-list* in the call augmented by the addition of the left operand of the `.` operator in the normalized member function call as the implied object argument (13.133.1).

1

In unqualified function calls, the name is not qualified by an `->` or `.` operator and has the more general form of a *primary-expression*. The name is looked up in the context of the function call following the normal rules for name lookup in function calls (3.923). The function declarations found by that lookup constitute the set of candidate functions. Because of the rules for name lookup, the set of candidate functions consists (1) entirely of non-member functions or (2) entirely of member functions of some class `T`. In case (1), the argument list is the same as the *expression-list* in the call. In case (2), the argument list is the *expression-list* in the call augmented by the addition of an implied object argument as in a qualified function call. If the keyword `this` (9.508.1) is in scope and refers to class `T`, or a derived class of `T`, then the implied object argument is `(*this)`. If the keyword `this` is not in scope or refers to another class, then a contrived object of type `T` becomes the implied object argument[127]. If the argument list is augmented by a contrived object and overload resolution selects one of the non-static member functions of `T`, the call is ill-formed.

13.250.0.0.1 Call to object of class type [over.call.object]

1

If the *primary-expression* `E` in the function call syntax evaluates to a class object of type "*cv* `T`", then the set of candidate functions includes at least the function call operators of `T`. The function call operators of `T` are obtained by ordinary lookup of the name `operator()` in the context of `(E).operator()`.

1

In addition, for each non-explicit conversion function declared in `T` of the form

> `operator` *conversion-type-id* `()` *cv-qualifier* *ref-qualifier*$_{opt}$ *exception-specification*$_{opt}$ *attribute-specifier-seq*$_{opt}$`;`

where *cv-qualifier* is the same cv-qualification as, or a greater cv-qualification than, *cv*, and where *conversion-type-id* denotes the type "pointer to function of `(P1,...,Pn)` returning `R`", or the type "reference to pointer to function of `(P1,...,Pn)` returning `R`", or the type "reference to function of `(P1,...,Pn)` returning `R`", a *surrogate call function* with the unique name *call-function* and having the form

> `R` *call-function* `(` *conversion-type-id* `F, P1 a1, ... ,Pn an) { return F (a1,... ,an); }`

is also considered as a candidate function. Similarly, surrogate call functions are added to the set of candidate functions for each non-explicit conversion function declared in a base class of `T` provided the function is not hidden within `T` by another intervening declaration[128].

1

If such a surrogate call function is selected by overload resolution, the corresponding conversion function will be called to convert `E` to the appropriate function pointer or reference, and the function will then be invoked with the arguments of the call. If the conversion function cannot be called (e.g., because of an ambiguity), the program is ill-formed.

1 The argument list submitted to overload resolution consists of the argument expressions present in the function call syntax preceded by the implied object argument `(E)`. [*Note:* When comparing the call against

127) An implied object argument must be contrived to correspond to the implicit object parameter attributed to member functions during overload resolution. It is not used in the call to the selected function. Since the member functions all have the same implicit object parameter, the contrived object will not be the cause to select or reject a function.

128) Note that this construction can yield candidate call functions that cannot be differentiated one from the other by overload resolution because they have identical declarations or differ only in their return type. The call will be ambiguous if overload resolution cannot select a match to the call that is uniquely better than such undifferentiable functions.

the function call operators, the implied object argument is compared against the implicit object parameter of the function call operator. When comparing the call against a surrogate call function, the implied object argument is compared against the first parameter of the surrogate call function. The conversion function from which the surrogate call function was derived will be used in the conversion sequence for that parameter since it converts the implied object argument to the appropriate function pointer or reference required by that first parameter. — *end note*] [*Example:*

```
int f1(int);
int f2(float);
typedef int (*fp1)(int);
typedef int (*fp2)(float);
struct A {
  operator fp1() { return f1; }
  operator fp2() { return f2; }
} a;
int i = a(1);        // calls f1 via pointer returned from
                     // conversion function
```

— *end example*]

13.264.0.1 Operators in expressions [over.match.oper]

1

If no operand of an operator in an expression has a type that is a class or an enumeration, the operator is assumed to be a built-in operator and interpreted according to Clause 5. [*Note:* Because `.`, `.*`, and `::` cannot be overloaded, these operators are always built-in operators interpreted according to Clause 5. `?:` cannot be overloaded, but the rules in this subclause are used to determine the conversions to be applied to the second and third operands when they have class or enumeration type (5.3337). — *end note*] [*Example:*

```
struct String {
  String (const String&);
  String (const char*);
  operator const char* ();
};
String operator + (const String&, const String&);

void f(void) {
 const char* p= "one" + "two";  // ill-formed because neither
                                // operand has class or enumeration type
 int I = 1 + 1;                 // Always evaluates to 2 even if
                                // class or enumeration types exist that
                                // would perform the operation.
}
```

— *end example*]

1

If either operand has a type that is a class or an enumeration, a user-defined operator function might be declared that implements this operator or a user-defined conversion can be necessary to convert the operand to a type that is appropriate for a built-in operator. In this case, overload resolution is used to determine which operator function or built-in operator is to be invoked to implement the operator. Therefore, the operator notation is first transformed to the equivalent function-call notation as summarized in Table 11 (where `@` denotes one of the operators covered in the specified subclause).

1

Table 11 — Relationship between operator and function call notation

Subclause	Expression	As member function	As non-member function
13.1166.1	@a	(a).operator@ ( )	operator@ (a)
13.1170.1	a@b	(a).operator@ (b)	operator@ (a, b)
13.1178.1	a=b	(a).operator= (b)	
13.1210.1	a[b]	(a).operator[](b)	
13.1217.1	a->	(a).operator-> ( )	
13.1232.1	a@	(a).operator@ (0)	operator@ (a, 0)

For a unary operator `@` with an operand of a type whose cv-unqualified version is `T1`, and for a binary operator `@` with a left operand of a type whose cv-unqualified version is `T1` and a right operand of a type whose cv-unqualified version is `T2`, three sets of candidate functions, designated *member candidates*, *non-member candidates* and *built-in candidates*, are constructed as follows:

— If `T1` is a complete class type or a class currently being defined, the set of member candidates is the result of the qualified lookup of `T1::operator@` (13.230.0.1.1); otherwise, the set of member candidates is empty.

— The set of non-member candidates is the result of the unqualified lookup of `operator@` in the context of the expression according to the usual rules for name lookup in unqualified function calls (3.1092.1) except that all member functions are ignored. However, if no operand has a class type, only those non-member functions in the lookup set that have a first parameter of type `T1` or "reference to (possibly cv-qualified) `T1`", when `T1` is an enumeration type, or (if there is a right operand) a second parameter of type `T2` or "reference to (possibly cv-qualified) `T2`", when `T2` is an enumeration type, are candidate functions.

— For the operator `,`, the unary operator `&`, or the operator `->`, the built-in candidates set is empty. For all other operators, the built-in candidates include all of the candidate operator functions defined in 13.1258 that, compared to the given operator,
  — have the same operator name, and
  — accept the same number of operands, and
  — accept operand types to which the given operand or operands can be converted according to 13.779.0.1, and
  — do not have the same parameter-type-list as any non-member candidate that is not a function template specialization.

1

For the built-in assignment operators, conversions of the left operand are restricted as follows:

— no temporaries are introduced to hold the left operand, and

— no user-defined conversions are applied to the left operand to achieve a type match with the left-most parameter of a built-in candidate.

1 For all other operators, no such restrictions apply.

2

The set of candidate functions for overload resolution is the union of the member candidates, the non-member candidates, and the built-in candidates. The argument list contains all of the operands of the operator. The best function from the set of candidate functions is selected according to 13.530.1 and 13.562.1.[129] [*Example:*

129) If the set of candidate functions is empty, overload resolution is unsuccessful.

```
struct A {
  operator int();
};
A operator+(const A&, const A&);
void m() {
  A a, b;
  a + b;            // operator+(a,b) chosen over int(a) + int(b)
}
```

— *end example*]

1

If a built-in candidate is selected by overload resolution, the operands of class type are converted to the types of the corresponding parameters of the selected operation function, except that the second standard conversion sequence of a user-defined conversion sequence (13.844.0.0.1) is not applied. Then the operator is treated as the corresponding built-in operator and interpreted according to Clause 5. [*Example:*

```
struct X {
  operator double();
};

struct Y {
  operator int*();
};

int *a = Y() + 100.0;       // error: pointer arithmetic requires integral operand
int *b = Y() + X();         // error: pointer arithmetic requires integral operand
```

— *end example*]

1

The second operand of operator `->` is ignored in selecting an `operator->` function, and is not an argument when the `operator->` function is called. When `operator->` returns, the operator `->` is applied to the value returned, with the original second operand.[130]

1

If the operator is the operator `,`, the unary operator `&`, or the operator `->`, and there are no viable functions, then the operator is assumed to be the built-in operator and interpreted according to Clause 5.

1

[*Note:* The lookup rules for operators in expressions are different than the lookup rules for operator function names in a function call, as shown in the following example:

```
struct A { };
void operator + (A, A);

struct B {
  void operator + (B);
  void f ();
};

A a;
```

130) If the value returned by the `operator->` function has class type, this may result in selecting and calling another `operator->` function. The process repeats until an `operator->` function returns a value of non-class type.

```
void B::f() {
  operator+ (a,a);          // error: global operator hidden by member
  a + a;                    // OK: calls global operator+
}
```

— *end note*]

13.354.0.1 Initialization by constructor [over.match.ctor]

1

When objects of class type are direct-initialized (8.821), or copy-initialized from an expression of the same or a derived class type (8.821), overload resolution selects the constructor. For direct-initialization, the candidate functions are all the constructors of the class of the object being initialized. For copy-initialization, the candidate functions are all the converting constructors (12.708.1) of that class. The argument list is the *expression-list* or *assignment-expression* of the *initializer*.

13.368.0.1 Copy-initialization of class by user-defined conversion [over.match.copy]

1

Under the conditions specified in 8.821, as part of a copy-initialization of an object of class type, a user-defined conversion can be invoked to convert an initializer expression to the type of the object being initialized. Overload resolution is used to select the user-defined conversion to be invoked. [*Note:* The conversion performed for indirect binding to a reference to a possibly cv-qualified class type is determined in terms of a corresponding non-reference copy-initialization. — *end note*] Assuming that "*cv1* `T`" is the type of the object being initialized, with `T` a class type, the candidate functions are selected as follows:

— The converting constructors (12.708.1) of `T` are candidate functions.

— When the type of the initializer expression is a class type "*cv* `S`", the non-explicit conversion functions of `S` and its base classes are considered. When initializing a temporary to be bound to the first parameter of a constructor that takes a reference to possibly *cv*-qualified `T` as its first argument, called with a single argument in the context of direct-initialization of an object of type "*cv2* `T`", explicit conversion functions are also considered. Those that are not hidden within `S` and yield a type whose cv-unqualified version is the same type as `T` or is a derived class thereof are candidate functions. Conversion functions that return "reference to `X`" return lvalues or xvalues, depending on the type of reference, of type `X` and are therefore considered to yield `X` for this process of selecting candidate functions.

1

In both cases, the argument list has one argument, which is the initializer expression. [*Note:* This argument will be compared against the first parameter of the constructors and against the implicit object parameter of the conversion functions. — *end note*]

13.396.0.1 Initialization by conversion function [over.match.conv]

1

Under the conditions specified in 8.821, as part of an initialization of an object of nonclass type, a conversion function can be invoked to convert an initializer expression of class type to the type of the object being initialized. Overload resolution is used to select the conversion function to be invoked. Assuming that "*cv1* `T`" is the type of the object being initialized, and "*cv* `S`" is the type of the initializer expression, with `S` a class type, the candidate functions are selected as follows:

— The conversion functions of `S` and its base classes are considered. Those non-explicit conversion functions that are not hidden within `S` and yield type `T` or a type that can be converted to type `T` via a standard conversion sequence (13.837.0.0.1) are candidate functions. For direct-initialization, those explicit conversion functions that are not hidden within `S` and yield type `T` or a type that can be

converted to type `T` with a qualification conversion (4.246) are also candidate functions. Conversion functions that return a cv-qualified type are considered to yield the cv-unqualified version of that type for this process of selecting candidate functions. Conversion functions that return "reference to *cv2* `X`" return lvalues or xvalues, depending on the type of reference, of type "*cv2* `X`" and are therefore considered to yield `X` for this process of selecting candidate functions.

1 The argument list has one argument, which is the initializer expression. [*Note:* This argument will be compared against the implicit object parameter of the conversion functions. — *end note*]

13.413.0.1 Initialization by conversion function for direct reference binding [over.match.ref]

1

Under the conditions specified in 8.2156.1, a reference can be bound directly to a glvalue or class prvalue that is the result of applying a conversion function to an initializer expression. Overload resolution is used to select the conversion function to be invoked. Assuming that "*cv1* `T`" is the underlying type of the reference being initialized, and "*cv* `S`" is the type of the initializer expression, with `S` a class type, the candidate functions are selected as follows:

— The conversion functions of `S` and its base classes are considered. Those non-explicit conversion functions that are not hidden within `S` and yield type "lvalue reference to *cv2* `T2`" (when initializing an lvalue reference or an rvalue reference to function) or "*cv2* `T2`" or "rvalue reference to *cv2* `T2`" (when initializing an rvalue reference or an lvalue reference to function), where "*cv1* `T`" is reference-compatible (8.2156.1) with "*cv2* `T2`", are candidate functions. For direct-initialization, those explicit conversion functions that are not hidden within `S` and yield type "lvalue reference to *cv2* `T2`" or "*cv2* `T2`" or "rvalue reference to *cv2* `T2`," respectively, where `T2` is the same type as `T` or can be converted to type `T` with a qualification conversion (4.246), are also candidate functions.

1 The argument list has one argument, which is the initializer expression. [*Note:* This argument will be compared against the implicit object parameter of the conversion functions. — *end note*]

13.425.0.1 Initialization by list-initialization [over.match.list]

1

When objects of non-aggregate class type `T` are list-initialized (8.2435.1), overload resolution selects the constructor in two phases:

— Initially, the candidate functions are the initializer-list constructors (8.2435.1) of the class `T` and the argument list consists of the initializer list as a single argument.

— If no viable initializer-list constructor is found, overload resolution is performed again, where the candidate functions are all the constructors of the class `T` and the argument list consists of the elements of the initializer list.

If the initializer list has no elements and `T` has a default constructor, the first phase is omitted. In copy-list-initialization, if an `explicit` constructor is chosen, the initialization is ill-formed. [*Note:* This differs from other situations (13.354.0.1, 13.368.0.1), where only converting constructors are considered for copy-initialization. This restriction only applies if this initialization is part of the final result of overload resolution. — *end note*]

13.530.1 Viable functions [over.match.viable]

1

From the set of candidate functions constructed for a given context (13.133.1), a set of viable functions is chosen, from which the best function will be selected by comparing argument conversion sequences for the

best fit (13.562.1). The selection of viable functions considers relationships between arguments and function parameters other than the ranking of conversion sequences.

1

First, to be a viable function, a candidate function shall have enough parameters to agree in number with the arguments in the list.

— If there are m arguments in the list, all candidate functions having exactly m parameters are viable.

— A candidate function having fewer than m parameters is viable only if it has an ellipsis in its parameter list (8.360.1). For the purposes of overload resolution, any argument for which there is no corresponding parameter is considered to "match the ellipsis" (13.868.0.0.1) .

— A candidate function having more than m parameters is viable only if the *(m+1)*-st parameter has a default argument (8.545.1).[131] For the purposes of overload resolution, the parameter list is truncated on the right, so that there are exactly m parameters.

1

Second, for `F` to be a viable function, there shall exist for each argument an *implicit conversion sequence* (13.779.0.1) that converts that argument to the corresponding parameter of `F`. If the parameter has reference type, the implicit conversion sequence includes the operation of binding the reference, and the fact that an lvalue reference to non-`const` cannot be bound to an rvalue and that an rvalue reference cannot be bound to an lvalue can affect the viability of the function (see 13.870.0.0.1).

13.562.1 Best viable function [over.match.best]

1

Define ICSi(`F`) as follows:

— if `F` is a static member function, ICS*1*(`F`) is defined such that ICS*1*(`F`) is neither better nor worse than ICS*1*(`G`) for any function `G`, and, symmetrically, ICS*1*(`G`) is neither better nor worse than ICS*1*(`F`)[132]; otherwise,

— let ICSi(`F`) denote the implicit conversion sequence that converts the i-th argument in the list to the type of the i-th parameter of viable function `F`. 13.779.0.1 defines the implicit conversion sequences and 13.946.0.1 defines what it means for one implicit conversion sequence to be a better conversion sequence or worse conversion sequence than another.

Given these definitions, a viable function `F1` is defined to be a *better* function than another viable function `F2` if for all arguments i, ICSi(`F1`) is not a worse conversion sequence than ICSi(`F2`), and then

— for some argument j, ICSj(`F1`) is a better conversion sequence than ICSj(`F2`), or, if not that,

— the context is an initialization by user-defined conversion (see 8.821, 13.396.0.1, and 13.413.0.1) and the standard conversion sequence from the return type of `F1` to the destination type (i.e., the type of the entity being initialized) is a better conversion sequence than the standard conversion sequence from the return type of `F2` to the destination type. [*Example:*

```
struct A {
  A();
  operator int();
```

131) According to 8.545.1, parameters following the *(m+1)*-st parameter must also have default arguments.

132) If a function is a static member function, this definition means that the first argument, the implied object argument, has no effect in the determination of whether the function is better or worse than any other function.

```
  operator double();
} a;
int i = a;                    // a.operator int() followed by no conversion
                              // is better than a.operator double() followed by
                              // a conversion to int
float x = a;                  // ambiguous: both possibilities require conversions,
                              // and neither is better than the other
```

— *end example*] or, if not that,

— the context is an initialization by conversion function for direct reference binding (13.413.0.1) of a reference to function type, the return type of `F1` is the same kind of reference (i.e. lvalue or rvalue) as the reference being initialized, and the return type of `F2` is not [*Example:*

```
template <class T> struct A {
  operator T&();        // #1
  operator T&&();       // #2
};
typedef int Fn();
A<Fn> a;
Fn& lf = a;             // calls #1
Fn&& rf = a;            // calls #2
```

— *end example*] or, if not that,

— `F1` is not a function template specialization and `F2` is a function template specialization, or, if not that,

— `F1` and `F2` are function template specializations, and the function template for `F1` is more specialized than the template for `F2` according to the partial ordering rules described in 14.992.0.1.

1

If there is exactly one viable function that is a better function than all other viable functions, then it is the one selected by overload resolution; otherwise the call is ill-formed[133].

[*Example:*

```
void Fcn(const int*,  short);
void Fcn(int*, int);

int i;
short s = 0;

void f() {
  Fcn(&i, s);                 // is ambiguous because
                              // &i → int* is better than &i → const int*
                              // but s → short is also better than s → int

  Fcn(&i, 1L);                // calls Fcn(int*, int), because
                              // &i → int* is better than &i → const int*
                              // and 1L → short and 1L → int are indistinguishable
```

133) The algorithm for selecting the best viable function is linear in the number of viable functions. Run a simple tournament to find a function `W` that is not worse than any opponent it faced. Although another function `F` that `W` did not face might be at least as good as `W`, `F` cannot be the best function because at some point in the tournament `F` encountered another function `G` such that `F` was not better than `G`. Hence, `W` is either the best function or there is no best function. So, make a second pass over the viable functions to verify that `W` is better than all other functions.

```
  Fcn(&i,'c');                    // calls Fcn(int*, int), because
                                  // &i → int* is better than &i → const int*
                                  // and c → int is better than c → short
}
```

— *end example*]
